In general, maternal infection shortly before conception does not lead to intrauterine infection.⁶³ However, when infection occurs after conception, the virus is present in placental villi approximately 10 days after the onset of rash in the mother and can be detected in the fetus after 20 to 30 days.¹¹³ Transplacental transmission occurs in up to 90% of cases during the first 8 weeks of gestation, falling to a low of 25% to 35% during the second trimester and rising again near term.^{7,75,251} This fluctuating incidence of fetal infection is likely related to changes in the placenta during pregnancy. In early gestation, infection of the placenta causes scattered foci of necrotic syncytiotrophoblast and cytotrophoblast cells, as well as damage to the vascular endothelium, resulting in placental hypoplasia.⁷⁵ Infection at later stages is associated with multifocal mononuclear cell infiltrates in the placental membranes, cord, and decidua, along with vasculitis.²⁵¹ In cases where fetal infection occurs, the virus can spread widely and almost any organ may be infected. A chronic and generally nonlytic infection is then established in the fetus.¹⁸⁷

Clinical Consequences

The effects of RV invasion of fetal tissue are quite varied, and early infection may result in resorption of the embryo. Whether placental infection alone can lead to spontaneous abortion or abnormalities of fetal development is not established. In the majority of cases, the infected fetus will survive and the pregnancy continues to term, with premature delivery or stillbirths being rare outcomes.¹⁵³ In many countries, clinically recognized maternal rubella during the first 8 weeks of gestation is an indication for therapeutic abortion due to the high incidence of congenital defects. Although these are not universal, some degree of neurologic deficit including sensorineural deafness is found in most cases. The current rubella vaccine RA27/3 has extremely low teratogenicity, and inadvertent vaccination in early pregnancy is not considered an indication for therapeutic abortion, although immunization at this time should be avoided.^{31,191}

The most common clinical manifestations of congenital rubella are listed in Table 24.1. In addition to the high incidence of sensorineural deafness (~80%), cataracts are detected in 50% to 60% of neonates infected in the first 8 weeks of pregnancy.⁷ Congenital heart disease is also found in more than half of CRS babies, usually manifested as patent ductus arteriosus or pulmonary artery or valvular stenosis. Other common defects include glaucoma, retinopathy, psychomotor retardation, neonatal thrombocytopenia purpura, hepatomegaly and/or splenomegaly, and intrauterine growth retardation.⁵² Less frequent features (present in 5% to 10%) include adenopathy, bony radiolucencies, hepatitis, and hemolytic anemia. Many of the clinical manifestations of congenital rubella are evident at birth or shortly thereafter. This includes a reddish-blue (purpuric) maculopapular rash termed the *blueberry muffin* rash (Fig. 24.14). Other clinical

TABLE 24.1 Manifestations of Congenital Rubella Syndrome

Group A	Group B
Eye manifestations	Purpura
• Cataracts	Hepatosplenomegaly
• Congenital glaucoma	Jaundice
• Retinitis	Microcephaly
Congenital heart defects	Meningoencephalitis
• Patent ductus arteriosus	Radiolucent bone disease
• Pulmonary artery stenosis	Progressive or late-onset manifestations
Sensorineural hearing loss	• Mental retardation
Pigmentary neuropathy	• Diabetes mellitus
	• Progressive panencephalitis

cal signs, including hepatosplenomegaly and jaundice, usually resolve within weeks. In addition, there are defects that are not recognized at birth but may be manifest in childhood (e.g., mental or physical retardation) or in adolescence (type 1 diabetes).

At birth, CRS is accompanied by clinical signs that include bulging anterior fontanel, microcephaly, lethargy, irritability, and motor tone abnormalities.²⁵¹ RV can be isolated from almost any organ at birth and from selected tissues for up to 1 year or more in surviving infants.¹⁵¹ More than 80% of congenitally infected newborns contain substantial amounts of RV in their nasopharyngeal secretions and urine, and 3% will continue to shed virus for as long as 20 months. This chronic shedding of RV by neonates is an indicator of early gestational infection⁵⁶ and a major source of virus for dissemination to others.

Mechanisms of Teratogenesis

Most of our information on rubella embryopathy comes from careful pathologic analyses conducted following the major

FIGURE 24.14. Infant with congenital rubella showing characteristic “blueberry muffin” maculopapular rash. (From Dermatology Online Journal, dermatology.cdlb.org.)

rubella pandemic of the 1960s. Data from these studies led to the idea that direct cytolytic effects of RV to cells in the retinal epithelium, myocardium, skeletal muscle, and neural tissue underlie much of the observed damage in CRS.^{117,210,233} The widespread nature of the tissue damage indicates that RV infects most fetal organ systems. Infection of focal clones of cells and their progeny during critical stages of the ontogeny of fetal organs was believed to give rise to the wide range of abnormalities that together compose CRS.

Because there are no animal models that recapitulate the teratogenic effects of RV infection, direct effects on human fetal cells *in situ* can only be extrapolated from studies in cell culture. Multiple studies reporting that cultured cells infected with RV exhibited signs of apoptosis^{61,100,122,149,195} and that human embryonic cells persistently infected with RV produce lower levels of collagen and are less responsive to epidermal growth factor²⁶¹ led to the hypothesis that altered cell physiology and induction of programmed cell death were integral to the teratogenic activity of the virus. However, a later study reported that RV infection does not induce apoptosis in human embryonic fibroblasts, but rather induces expression of multiple of antiapoptotic genes.³ These findings are consistent with a more recent report showing that the capsid protein blocks apoptosis in human embryonic and adult cultured cell lines.¹⁰⁷ Accordingly, it is quite possible that a predominantly noncytopathic RV infection of selected embryonic cell types *in utero* upsets the normal delicate balance of cellular growth and differentiation and has profound effects on organogenesis. These effects, alone or in concert, could explain the observation that the small but otherwise apparently normal organs of congenital rubella infants contain reduced numbers of cells.¹⁶¹ In addition to these direct effects of RV replication in host tissue, it is possible that immune-mediated damage occurs in CRS.

Fetal Immune Response in CRS

The persistence of RV in fetal tissue throughout gestation, and in infants with CRS for prolonged periods after birth, raises the question of how the virus avoids immune elimination. Clearly, neither transferred maternal IgG nor fetal IgM (detected at around 15 weeks' gestation²⁵¹) can eliminate virus *in utero*, although both have neutralizing capacity *in vitro*.⁵³ It has been suggested that antibody may in fact promote persistence; however, this phenomenon has only been observed *in vitro*.^{1,34} and it is not at all clear whether it can occur in the absence of the complement system and phagocytic cells. Two recent studies^{3,107} suggest that the ability of RV to block apoptosis may also play a role in establishment and/or maintenance of persistence by thwarting innate antiviral defenses. Moreover, because the thymus does not mature until 15 weeks, the fetus is highly vulnerable to viral infection prior to this time. Interferon- α is present early in gestation and therefore may limit viral spread, a scenario that could explain why only 0.1% to 0.001% of cells from fetal organs contain detectable virus.²⁰³

Postnatal infection induces IgG class antibodies against each of the three structural proteins of the virus; however, CRS infants often lack antibodies to the capsid protein and demonstrate weak humoral reactivity to the E2 protein.^{59,197} Perhaps more telling, these children show selective tolerance to the E1 protein¹⁴⁶ and, more specifically, possess little or no antibody to the putative E1 neutralization domain.^{157,197}

Infants with CRS also demonstrate prolonged impairment of RV-specific cell-mediated immune responses, including cytotoxicity, and lymphokine secretion *in vitro*.^{26,59} T-cell lines derived from several congenital rubella children and adults failed to respond to RV peptides that stimulate lymphocyte proliferative responses in normal immune adult donor cells.¹⁷² These data suggest that early fetal infection results in selective immune tolerance to a limited but critical number of RV epitopes that must be recognized to clear the virus.

Late-Onset Sequelae

Although many of the effects of fetal rubella that manifest at birth are transient, some defects such as retinopathy, mental retardation, hearing loss, and endocrine abnormalities may not become clinically apparent for several years.^{148,215} Psychomotor retardation (62%), cardiac abnormalities (58%), and mental retardation (42%) are also associated with CRS, and multi-organ disease is found in 88% of patients.⁷⁸

DELAYED ENDOCRINE DISEASE

Congenital RV infection is associated with a variety of delayed endocrine abnormalities, including type 1 diabetes, thyroid disease, and polyglandular autoimmunity.^{201,215} Early reports suggested that type 1 diabetes occurs in as many as 10% to 40% of CRS patients. However, while more recent analyses from a diabetes-focused perspective confirmed that *in utero* RV infection undoubtedly predisposes to diabetes, the proportion is probably less than 10%.⁷² Conversely, postnatal rubella does not have a clear association with type 1 diabetes.²³

The mechanism by which RV causes diabetes is not understood, and certainly the lack of a suitable animal model has limited progress in this area. However, a number of older studies in hamsters have provided some intriguing results. For example, Syrian hamster pups infected with an adapted rubella RA 27/3 vaccine virus exhibited hypoinsulinemia and hyperglycemia.²⁰⁴ In these animals, cell-free RV was recoverable from pancreas, viral antigens were present in islet cells, and a mononuclear infiltration of the islets occurred over the first 3 weeks of the infection. Moreover, islet cell antibodies developed in 40% of the infected pups.

RV-induced damage to the pancreas may therefore be a combination of viral replication in islets, compounded by the triggering of an autoimmune reaction that perpetuates beta-cell damage. Evidence in favor of this theory includes the identification of a monoclonal antibody to RV capsid protein that reacts with pancreatic islet cell Ia2 protein.¹¹² In addition, CD4 and CD8 T-cell clones isolated from CRS patients recognize peptides of the diabetes-associated autoantigen GAD65 in an HLA-restricted manner.^{174,179} Also, 20% to 40% of sera from CRS patients in a selected series were found to contain antibodies that react with thyroid tissue.^{48,77,216} Finally, CRS is also associated with growth hormone deficiency, and therefore, pituitary involvement is another complication. Relatedly, hamsters immunized with recombinant RV E1 or E2 develop pituitary autoantibodies.²⁶² In summary, these observations suggest that viral-induced autoimmunity may partially account for the late appearance of polyendocrine diseases that frequently complicate congenital rubella.

DELAYED NEUROLOGIC DISEASE

A rare late-onset encephalitis following rubella has been described, referred to as progressive rubella panencephalitis

(PRP).^{234,252} Like other slow viral diseases of the CNS, PRP is characterized by a prolonged asymptomatic period, followed by the onset of symptoms of neural deterioration during the second decade of life. The pathogenesis of PRP is unclear; however, immune complexes are consistently identified, suggesting ongoing viral replication.⁵⁵ The near-complete destruction of Purkinje cells indicates either some degree of selective tropism of RV for these cells within the CNS or a negative effect on their metabolism. This could also account for the selective loss of myelin and oligodendroglia, although immunopathologic mechanisms could also be active.

DIAGNOSIS

Differential

The most common symptoms of rubella (lymphadenopathy, erythematous rash, and low-grade fever) can be readily confused with similar illnesses associated with maculopapular rash caused by other common viral and nonviral pathogens or even some drug treatments. The differential diagnosis includes parvovirus, measles, human herpesvirus 6 (roseola), and rash-associated enteroviruses, such as echovirus 9 and coxsackievirus A9.⁷ In particular, parvovirus infections can be confused with rubella because their clinical presentations are so similar and both can be associated with arthritis or arthralgia.²¹⁷ Moreover, in endemic areas, dengue, West Nile, Sindbis, chikungunya, and Ross River virus infections should be considered.⁷ Therefore, a definitive diagnosis of rubella can only be made using specific laboratory tests.

Similarly, confirmation of a diagnosis of CRS cannot be established solely on the basis of clinical findings. It requires either the direct isolation of RV or serologic evidence of acute infection in the infant. In the absence of confirmatory laboratory data, a clinical diagnosis compatible with CRS requires the presence of any two of the following: cataracts and/or congenital glaucoma, congenital heart disease, hearing loss, or pigmentary retinopathy. In the presence of only one of the preceding manifestations, the additional finding of purpura, hepatosplenomegaly, jaundice, microcephaly, mental retardation, meningoencephalitis, or radiolucent bone disease is indicative of CRS (Table 24.1).³³ In countries in which rubella vaccination is not carried out (or is in the process of being implemented), surveillance for CRS is important to monitor for prevalence or effectiveness of the vaccination policy. A combination of eye and congenital heart anomalies has been proposed as a sensitive and specific sentinel for CRS to identify infants for further laboratory investigation.²⁰⁷

Laboratory

Diagnosis of postnatal rubella and congenital infection (following birth) is normally carried out by detection of rubella-specific IgM by enzyme immunoassay (EIA) using commercial assays.²³² The capture assay is preferred over indirect assays, which have been shown to give false-positive results with other acute viral infections such as parvovirus, Epstein-Barr virus, or cytomegalovirus,²²⁶ or when rheumatoid factor is present.⁸² IgM is usually detectable for 6 to 8 weeks after acute rubella⁷ but can be detected for longer in some patients and is present for up to a year in congenitally infected infants.²²⁷

Virus isolation may occasionally be warranted, particularly to confirm infection during pregnancy. In acute infection, RV is readily isolated from throat swabs or nasopharyngeal secretions for approximately 1 week before and up to 2 weeks after the appearance of rash.²⁶⁵ Virus can also be isolated from circulating lymphocytes for up to 1 month postinfection,³⁷ but this is too expensive for routine clinical diagnostic purposes. Cord blood or placental tissue may be used to confirm congenital infection at the time of birth. In addition, virus can readily be isolated from throat swabs or urine of the neonate.⁵⁶

Over the last 10 to 15 years, a variety of nucleic acid amplification-based techniques have been developed to detect RV genomic RNA in clinical samples. Reverse transcription of RNA isolated from patient tissue/cells or fluid is required prior to amplification of the cDNA by PCR using primers specific for a selected region of the RV genome (usually the *E1* gene). PCR-based detection of RV RNA has been used to detect virus in cases of suspected congenital infection using samples obtained by amniocentesis, cordocentesis, and chorionic villus sampling for *in utero* diagnosis.^{24,205} A comparison of nested RT-PCR on amniotic fluid with measurement of rubella IgM in fetal blood has confirmed both the specificity and the sensitivity of the genome amplification technique.¹³⁷ Finally, adaption of multiplexed real time-based PCR assays allows molecular genotyping as well as exquisitely accurate and sensitive detection of as little as one plaque-forming unit of RV in clinical samples.^{163,164}

PREVENTION AND CONTROL

Vaccines

Development

Following isolation of RV in cell culture in 1962,¹⁸² attenuation of the virus was carried out by serial passage in a variety of cell lines, giving rise to several vaccine strains that came into use around 1970. These included the original vaccine used widely in North America, HPV77/DE5²⁷; the Cendehill strain, used more extensively in Europe¹⁸⁵; and several Japanese strains.²¹⁸ The HPV77/DE5 strain was the predominant strain used in North America until 1979, when it was replaced by the RA27/3 vaccine due to concerns of waning immunity in HPV77/DE5 vaccine recipients.¹⁰³ The RA27/3 strain was derived from an isolate from the kidney of a RV-infected fetus and was attenuated by passaging 4 times in human embryonic kidney cells followed by passage 17 to 25 times in WI-38 fibroblasts.¹⁸⁸ This strain of virus induces a more vigorous immune response than HPV77/DE5 and has the added advantage that it was attenuated in human cells and is therefore not subject to possible side effects associated with vaccines grown in nonhuman cells. RA27/3 was licensed in 1979 and is now the only rubella vaccine available in North America. It is also widely used in other countries, including the majority of those in Europe, in Australia and New Zealand, and in South America. However, in parts of Asia, locally produced rubella vaccine strains are used. In Japan, five vaccine strains (KRT, TO-336, Matsuura, TCRB19, and Matsuba) have been developed,¹⁶⁹ whereas in China, BRD-2 has been compared in clinical studies to RA27/3.²⁴⁷ The most recent reporting indicates that 130 of the 193 World Health Organization (WHO) member states (Fig. 24.1) now employ RV vaccine in their national immunization programs.²⁹ Yet, this

does not include most of Africa and India and large areas of Asia, and as such, it represents less than 50% of the global birth cohort. The WHO initiated a campaign to eliminate rubella and CRS from the Americas by 2010 and the European region by 2015.

Vaccine Administration

Rubella vaccine is usually given in combination with measles and mumps as the measles-mumps-rubella (MMR) vaccine between 12 and 15 months of age, with a subsequent booster dose prior to school entry or in adolescence. Subcutaneous administration induces an antibody response in approximately 95% of recipients older than 12 months of age, detectable at 4 weeks postimmunization. The majority of vaccinated children report only mild symptoms, and transmission to susceptible bystanders seems not to occur. Although the antibody titers are lower than those following natural infection, protection is believed to endure for more than 21 years in the majority of those immunized.¹⁶⁸ However, in 10% of women tested in the United States, titers had dropped to low or undetectable levels in 5 years, although they responded rapidly to challenge with high-titer RA27/3.¹⁶⁷ In view of this, rubella vaccination should be given to all women of childbearing age found to have low or undetectable antibody titers, preferably 1 month before conception or postpartum. Immunization during pregnancy should be avoided (see Risk in Pregnancy section).

Adverse Reactions

The current RA27/3 vaccine is well tolerated but not problem free. Certainly, the incidence of acute adverse reactions is lower than after natural rubella²²⁹ but still higher than that reported for some other vaccine strains.²¹ Symptoms include fever, lymphadenopathy, arthralgia/arthritis, paresthesia, and carpal tunnel syndrome. Between 10% and 30% of adult rubella seronegative women vaccinated with the RA27/3 vaccine develop acute, usually transient, arthritis or arthralgia.^{189,229,231} The joint reactions can be recurrent or persistent, similar to symptoms following natural rubella, and viral persistence may be associated with ongoing symptoms.³⁵ Subsequent studies have questioned the link between RV vaccination and joint manifestations, and it is probably prudent to conclude that the incidence of vaccine-induced chronic arthritis is lower than previously reported.²²⁹ However, the finding of an association of certain HLA-DR haplotypes with a higher incidence of joint symptoms following RA27/3 rubella vaccination¹⁵⁵ suggests that the virus may cause joint symptoms in small numbers of genetically predisposed individuals. This factor should be taken into account in any future studies based on analysis of populations.

Vaccine side effects and complications are a serious challenge to maintaining herd immunity, and the higher incidence of arthralgia and arthritis particularly in female vaccines has most certainly had negative consequences. However, by far the most damage to effective uptake of MMR vaccine stems from a report by Wakefield et al²⁴⁵ that ultimately led to the belief among a significant number of people that this vaccine was linked to autism. Numerous larger and much better controlled studies failed to confirm a causal relationship between the MMR vaccine and autism, but unfortunately the damage was done and the rate of vaccine uptake dropped dramatically. Predictably, this led to an increase in the number of cases of measles and, to a lesser extent, rubella. Fortunately, the journal that

published the Wakefield et al paper, the *Lancet*, retracted the paper from the published record in 2010. However, it will still be some time before we have fully recovered from the effects of this fraudulent report.

Risk in Pregnancy

A serious concern of rubella vaccination programs has been the potential risk to the developing fetus in mothers who are immunized during early pregnancy. In such instances, the placenta and fetus may become infected, although the isolation rate is only 3%.²⁰⁸ Moreover, one survey of 515 children born of mothers inadvertently immunized within 3 months of conception showed that none had malformations compatible with CRS.²⁰ This included cases of vaccination with the earlier Cendehill and HPV-77 vaccines, as well as with the current RA27/3 vaccine. Vaccine strains of RV therefore appear to be far less teratogenic than wt+ RV, and even in one case where the fetus was infected no signs of CRS were detected at birth. Because a potential risk to the fetus still exists (estimated at 1.3% when the mother is vaccinated 1 to 2 weeks before to 4 to 6 weeks after conception³²), pregnancy remains a contraindication to rubella vaccination. However, inadvertent vaccination of a seronegative pregnant woman is not sufficient reason for termination of pregnancy.

New Vaccine Strategies

Because the current rubella vaccines are considered highly effective, there is limited interest in developing a subunit vaccine. Nevertheless, live attenuated vaccines are not recommended for children with immunodeficiency diseases or for women in the early stages of pregnancy who might be living or working in a situation where they risk exposure. For these situations, a subunit vaccine that provides some protection, even if only for a limited time, may be appropriate. Use of the E1 protein, which contains the major neutralizing epitopes, has been proposed,²⁵⁷ but such vaccine platforms have not been developed further. In addition, DNA vaccines incorporating genes for all three structural proteins, or just E1 and E2, have been constructed and have shown some promise in mice.¹⁹⁰ However, for general use, a live attenuated vaccine that promotes the strongest and most enduring immune response is still advisable. With current knowledge on the genetic determinants of virulence and joint tropism, the potential exists for development of a recombinant vaccine designed to be highly immunogenic but not associated with unwanted side effects. Nevertheless, the overall success of current vaccines likely precludes further development of next-generation recombinant vaccines.

PERSPECTIVE

With the availability of relatively inexpensive and safe vaccines, rubella is most certainly a preventable disease. Indeed, much of the industrialized world has adopted comprehensive immunization policies that have curtailed virus circulation and CRS; however, more than 50% of the global birth cohort is still susceptible to rubella.²⁹ The cost of medical care for children with CRS easily justifies implementation of comprehensive immunization programs on economic grounds alone.⁸⁹ Yet RV is still endemic in many developing countries, and sadly, these are the least well-equipped nations to deal with the very high costs of caring for CRS children.

Compounding matters is the fact that to prevent RV transmission, herd immunity needs to exceed 85%⁴ and the cost of proper surveillance for RV can be prohibitive. As a result of inadequate surveillance, the actual numbers of rubella and CRS are vastly underreported. For example, based on seroprevalence data and statistical modeling for the Southeast Asia region, it is estimated that more than 46,000 infants are born with CRS each year, yet only 13 cases of CRS were reported between 2000 and 2009.²⁹ Accordingly, RV is still a significant human pathogen that takes an enormous toll on the health of the world's population through the widespread manifestations of CRS, most notably in relation to blindness and hearing defects.

On the positive side, significant progress has been made with respect to understanding virus–host interactions at the molecular level, and the complete sequences of multiple wild-type and vaccine strains of RV are known. By pooling the knowledge from these studies through further investigation, we will be in a better position to understand the underlying mechanisms of teratogenicity and virus-induced autoimmune diseases such as diabetes and arthritis.

INTRODUCTION

The first human virus was discovered over one century ago when Walter Reed demonstrated that yellow fever could be experimentally transferred via the filtered serum of an infected individual, and that this infectious agent was transmitted to humans by mosquitoes.⁸¹⁷ It is now appreciated that yellow fever virus (YFV) is but one representative of a large family of related positive-strand RNA viruses, the *Flaviviridae* (from the Latin *flavus*, “yellow”). This family currently consists of three genera: *Flavivirus*, *Pestivirus* (from the Latin *pestis*, “plague”), and *Hepacivirus* (from the Greek *hepar*, *hepatos*, “liver”).⁸⁵¹ (Table 25.1). A fourth genus, *Pegivirus* (persistent GB virus), has recently been proposed to encompass the previously unclassified GB virus A (GBV-A), GBV-C, and GBV-D.⁸⁰⁵ As detailed later, the *Flaviviridae* share similarities in virion morphology, genome organization, and replication strategy but exhibit diverse biological properties and lack serologic cross-reactivity. The phylogenetic relationships of the *Flaviviridae* are shown in Figure 25.1. The increasing significance of *Flaviviridae* as human and animal pathogens emphasizes that their study remains no less pertinent than in Reed’s time.

Family Classification

Positive-stranded RNA viruses are classified into three superfamilies based on the evolutionary relatedness of their RNA-dependent RNA polymerases (RdRPs). The *Flaviviridae* are members of superfamily 2, bearing distant similarity to coliphages and the plant-infecting carmo-, tombus-, diantho-, and subgroup I luteoviruses.⁴¹⁸ Before the era of molecular biology, some members of the family *Flaviviridae* were classified as *Togaviridae*.

Family Characteristics and Replication Cycle

This chapter is organized around common features of the family *Flaviviridae* life cycle (Fig. 25.2). The enveloped virions are composed of a lipid bilayer with two or more species of envelope (E) glycoprotein surrounding a nucleocapsid, which consists of a single-stranded, positive-sense RNA genome complexed with multiple copies of a small, basic capsid (C) protein. Binding and uptake are believed to involve receptor-mediated endocytosis. The low pH of the endosome induces fusion of the virion envelope with cellular membranes. Following uncoating of the nucleocapsid, the RNA genome is released into the cytoplasm. The genome serves three discrete roles within the life cycle: as the messenger RNA (mRNA) for translation of all viral proteins, a template during RNA replication, and the genetic material packaged within new virus particles. The organization

TABLE 25.1 Members of the *Flaviviridae*

Taxonomic unit	Representative examples
Genus <i>Flavivirus</i> ⁵⁴	
Mosquito-borne viruses	<i>Yellow fever virus</i> (YFV) <i>Dengue virus</i> , types 1 to 4 (DENV-1 to DENV-4) <i>Japanese encephalitis virus</i> (JEV) <i>Kokobera virus</i> (KOKV) <i>West Nile virus</i> (WNV)
Tick-borne viruses	<i>Tick-borne encephalitis virus</i> , European subtype (TBEV-Eu) <i>Tick-borne encephalitis virus</i> , Far Eastern subtype (TBEV-FE) <i>Omsk hemorrhagic fever virus</i> (OHFV) <i>Tyuleniy virus</i> (TYEV)
Viruses with no known vector	<i>Modoc virus</i> (MODV) <i>Rio Bravo virus</i> (RBV)
Unclassified	<i>Cell fusing agent virus</i> (CFAV)
Genus <i>Hepacivirus</i> ¹	<i>Hepatitis C virus</i> (HCV), seven genotypes <i>GB virus B</i> (GBV-B; unclassified) <i>Canine hepacivirus</i> (CHV; unclassified)
Genus <i>Pestivirus</i> ⁴	<i>Bovine viral diarrhea virus 1</i> (BVDV-1) <i>Bovine viral diarrhea virus 2</i> (BVDV-2) <i>Border disease virus</i> (BDV) <i>Classical swine fever virus</i> (CSFV) ^a <i>Giraffe-1 pestivirus</i> (unclassified)
Genus <i>Pegivirus</i> (proposed)	<i>GB virus A</i> (GBV-A) <i>GB virus C</i> (GBV-C), “ <i>Hepatitis G virus</i> (HGV)” <i>GB virus D</i> (GBV-D)

Numbers in superscript indicate the current number of virus species recognized within each group.

^aCSFV was formerly called *hog cholera virus* (HCV). The name was changed to avoid confusion with *hepatitis C virus*.

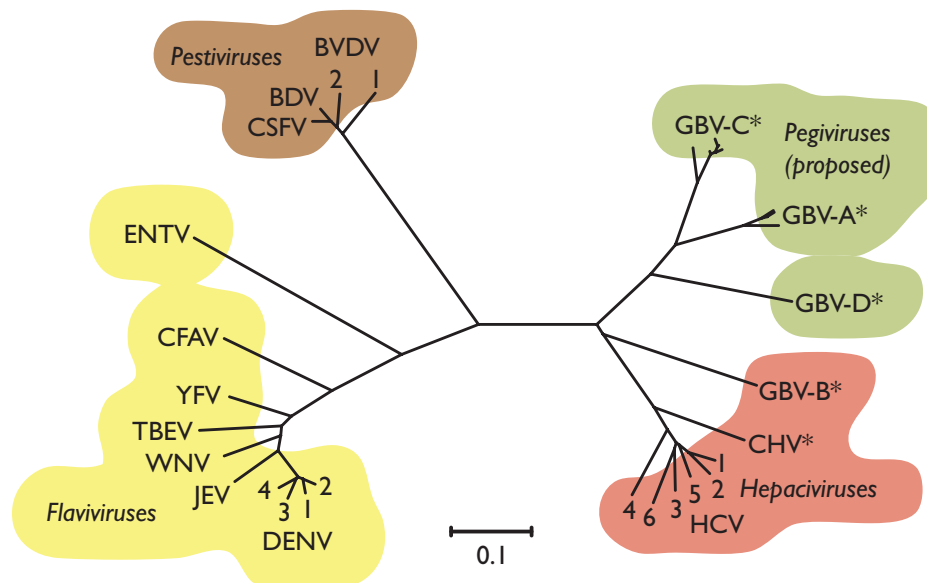

FIGURE 25.1. The family *Flaviviridae*. Phylogenetic tree based on neighbor-joining analysis of the viral RNA-dependent RNA polymerases (RdRPs). Shown are members of the *Flavivirus* genus: yellow fever virus (YFV), dengue virus (DENV) serotypes 1 through 4, West Nile virus (WNV), Japanese encephalitis virus (JEV), tick-borne encephalitis virus (TBEV), cell-fusing agent virus (CFAV), and Entebbe bat virus (ENTV); the *Pestivirus* genus: bovine viral diarrhea virus (BVDV) types 1 and 2, classical swine fever virus (CSFV), and border disease virus (BDV); the *Hepacivirus* genus: hepatitis C virus (HCV) genotypes 1 through 6, GB virus B (GBV-B, proposed assignment), and canine hepacivirus (CHV, proposed assignment); and the proposed *Pegivirus* genus: GB virus A (GBV-A), GB virus C (GBV-C), and GB virus D (GBV-D). The scale bar indicates amino acid substitutions per position.

FIGURE 25.2. The life cycle of the *Flaviviridae*. See text for further details.

of the genome is similar for all genera. Viral proteins are produced as part of a single polypeptide that is cleaved by a combination of host and viral proteases. The structural proteins are located in the N-terminal portion of the polypeptide with the nonstructural (NS) proteins in the remainder. Sequence motifs characteristic of a serine protease, RNA helicase, and an RdRP are found in similar locations in the polypeptides of all three genera.⁵⁸⁵ RNA replication occurs entirely in the cytoplasm in close association with intracellular membranes; the synthesis of a genome-length minus-strand RNA provides the intermediate. Progeny virions assemble by budding into an intracellular membrane compartment, most likely the endoplasmic reticulum (ER), then transit through the host secretory pathway and are released at the cell surface.

FLAVIVIRUSES

Background and Classification

The *Flavivirus* genus consists of more than 50 species, many of which are arthropod-borne human pathogens. Flaviviruses cause

a variety of diseases, including fever, encephalitis, and hemorrhagic fevers. Entities of major global concern include dengue virus (DENV)—with its associated dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS)—Japanese encephalitis virus (JEV), West Nile virus (WNV), and YFV (reviewed in⁵³⁷). Other flaviviruses with regional or endemic distribution include Murray Valley encephalitis virus (MVEV) and St. Louis encephalitis virus (SLEV). *Tick-borne encephalitis virus* (TBEV) is a name commonly applied to either central European encephalitis virus or Far Eastern encephalitis virus, although these are clearly distinct species.²⁰⁸ Decreases in mosquito control efforts during the latter part of the 20th century, coupled with societal factors (e.g., increased transportation and dense urbanization), have contributed to the re-emergence of flaviviruses such as DENV in South and Central America. Following an outbreak in New York City in 1999, WNV has spread throughout much of North America and Central America.

Flavivirus species are further categorized into antigenic complexes and subcomplexes based on serologic criteria or into clusters, clades, and species, according to molecular phylogenetics.¹¹⁷ Mosquito-borne and tick-borne flaviviruses, although

distinct, appear to have evolved via a common ancestral line that diverged from viruses with no known arthropod vector. DENV circulates as four distinct serotypes, which show significant sequence diversity (reviewed in³³⁷). Some reports have documented intertypic recombination among DENV isolates, although the taxonomic status of these isolates is currently unclear.

The development of the first live-attenuated flavivirus vaccine, YFV strain 17D,⁸⁴⁹ led to Max Theiler's recognition by the Nobel Prize committee in 1951. Only a limited number of flavivirus vaccines are available, including inactivated TBEV and JEV for use in humans and inactivated WNV for use in animals.⁶⁹⁴ Development of effective DENV vaccines that exhibit cross-protection between serotypes is proving to be particularly challenging. The ability to genetically manipulate flaviviruses has led to novel approaches, including live attenuated chimeric vaccines based on the YFV-17D backbone.

Structure and Physical Properties of the Virion

Infectious flavivirus particles are roughly spherical, approximately 50 nm in diameter, and surrounded by a lipid envelope⁶¹⁵ (Fig. 25.3). Viruses sediment between 170 and 210S and have buoyant densities of 1.19 to 1.23 g/cm³ depending on the lipid composition, which can vary by host.⁷⁴⁵ The outer shell of the particle is made up of two viral proteins, envelope (E) and membrane (M). The E glycoprotein is the major antigenic determinant of the virion and mediates binding and fusion during virus entry. The M protein is a small proteolytic fragment of the precursor (pr)M protein and is produced during viral maturation within the secretory pathway. Removal of the lipid envelope with nonionic detergents reveals discrete nucleocapsids (120 to 140S; 1.30 to 1.31 g/cm³), which consist of capsid (C) protein and genomic RNA (reviewed in⁷⁴⁵). Isolated nucleocapsids become unstable under high salt conditions, disassembling into C protein dimers.³⁹⁹

Cryo-electron microscopy and image reconstruction have provided a wealth of information on flavivirus structure. Mature infectious particles of DENV⁴³⁰ and WNV⁶¹⁰ display a relatively

smooth outer surface. Fitting the E protein crystal structure⁷²² into the electron density maps showed that glycoprotein dimers lie flat across the surface of the virion. Interestingly, the 180 copies of E are tightly packed in an unusual herringbone array that completely covers the lipid bilayer. Beneath the protein shell, the M protein associates closely with the membrane. Notably, the nucleocapsid lacks discernible symmetry, and neither E nor M sequences extend through the membrane to make contacts with the nucleocapsid.⁹⁵⁶

Immature flavivirus particles adopt various appearances as they egress through the secretory pathway.⁶⁶⁷ Soon after they are formed, immature virions are larger (60 nm in diameter) than mature virions and display 60 prominent spikes on their surface.⁹⁵⁷ Each protrusion is composed of three E-prM heterodimers, with the prM molecule capping the E fusion peptide. As immature particles pass through the low pH environment of the *trans*-Golgi network, a dramatic rearrangement of the glycoproteins occurs. The immature virions now adopt a smooth appearance almost indistinguishable from mature particles, with the exception that prM remains attached.⁹⁴⁶ This conformational change is followed by cleavage of prM by the host cell enzyme furin⁸⁰² and the release of the protective fragment upon exit from the cell, revealing the mature virions.⁹⁴⁶ This process is not always efficient, and immature or partially mature particles can be released in significant quantities. Although immature particles are deemed noninfectious because they cannot undergo fusion,³⁰³ they have recently been shown to initiate infection when internalized in complex with anti-prM antibodies by cells bearing the Fc receptor.⁷³⁵ The mechanism of this is not well understood, but it may invoke prM cleavage in the endosome and could be especially relevant during secondary infection when antibody levels are high. In addition, partially matured particles that retain only some prM have been visualized in flavivirus populations and can undergo attachment and fusion to initiate infection similar to fully mature particles.¹³⁷

Small, noninfectious subviral particles (SVPs) are the final class of particles released from flavivirus-infected cells. SVPs

Harrison.) **C:** Paracrystalline array of SLEV particles in the salivary gland of a *Culex pipiens* mosquito 25 days after blood meal feeding on an infected suckling mouse. (Courtesy of Sylvia G. Whitfield, Frederick A. Murphy, and W. Daniel Sudia.)

contain E and M proteins but lack C and RNA.⁷⁹⁷ They complete the same maturation process as whole virions and can undergo fusion with a target cell⁷⁶⁰; due to lack of a genome, however, they are not infectious. Recombinant subviral particles (RSPs) form in cells experimentally transfected with only prM and E, indicating that interactions between these envelope proteins are sufficient to drive budding.^{14,512,760} RSPs are generally about 30 nm in diameter and slightly less dense than infectious virus (1.14 g/cm³),⁷⁶⁰ although virion-sized particles have also been observed in these expression systems.^{16,512} Cryo-electron microscopy and image reconstruction of TBEV RSPs suggests a markedly different arrangement of the E proteins compared to infectious virions. Thirty E dimers lie flat against the surface in a $T = 1$ icosahedral shell²³² rather than a herringbone array.⁴³⁰ It is hypothesized that this arrangement may resemble a fusion intermediate that is adopted as E dimers rearrange to trimers upon virus entry.⁶¹¹

Binding and Entry (see Video in e-Book)

Flaviviruses infect a variety of target cells through receptor-mediated endocytosis, followed by intracellular membrane fusion. Flavivirus receptors are not well characterized, perhaps because these viruses use a range of entry factors for different cell types and employ more than one host molecule to enter a target cell. Highly sulphated glycosaminoglycans, such as heparin sulphate, are ubiquitously expressed molecules used as initial attachment factors by many viruses. These factors have also been shown to play a role in binding and entry of flaviviruses, such as DENV,¹³² YFV,²⁶⁹ TBE,⁴²⁶ and JEV.¹³⁰ However, high affinity for glycosaminoglycans in tissue culture-adapted strains is associated with *in vivo* attenuation.⁴⁵⁸ C-type lectins are cellular proteins that bind mannose-rich glycans and are involved in flavivirus infection of dendritic cells (DCs). Intradermal DCs are often the primary targets encountered by the arthropod-delivered pathogens and can transport the virus to draining lymph nodes where a second round of replication initiates viremia. C-type lectin Dendritic cell-specific intercellular adhesion molecule 3-grabbing nonintegrin (DC-SIGN) is thought to function as an attachment receptor for DENV infection of DCs.^{516,624,833} WNV preferentially uses DC-SIGN-related (DC-SIGNR),¹⁸² while YFV-17D, which lacks glycan modifications on E, can infect DC cells in a lectin-independent manner.³⁹ The mannose receptor is a C-type lectin that is constitutively internalized by clathrin-mediated endocytosis and has been suggested to play a role in endocytosis of DENV, JEV, and TBEV.⁵⁸⁴ Interestingly, C-type lectin domain family 5, member A (CLEC5) interacts with DENV but does not mediate its entry; instead, CLEC5 binding triggers the release of inflammatory cytokines, leading to DHF/DSS-like symptoms in mice.¹³¹

Additional receptors that have been implicated in flavivirus entry include the glycosphingolipid neolactotetraosylceramide,²⁶ low-density lipoprotein receptor (LDL-R),¹³⁸ laminin receptor 1,^{850,857} $\alpha\beta 3$ integrins,¹⁴⁴ and a CD14-containing complex.¹³⁴ Heat shock proteins have also been suggested as entry factors. GRP78 (BIP) plays a role in liver cell uptake of DENV,^{112,368} and Hsp90/Hsp70 acts in DENV and JEV entry into human monocytes/macrophages, neuroblastoma cell lines, and mosquito cells.^{180,720,723} Finally, virus particles opsonized with subneutralizing concentrations of immunoglobulins show enhanced binding and infection of cells expressing Fc receptors.^{661,764} It is widely speculated that antibody-enhanced

infection is relevant to the pathogenesis of DSS and DHF, which occur more frequently in people previously exposed to other DENV serotypes.

After capture by the appropriate receptor(s), flaviviruses are internalized by endocytosis. Single particle tracking of fluorescently labeled DENV particles has shown that virions diffuse across the surface of the cell until they encounter a preformed clathrin-coated pit.⁸⁷¹ Following internalization, DENV particles are delivered to early or intermediate endosomes, which then mature into late endosomes.⁸⁷¹ Fusion of the viral and host membranes occurs during endosomal trafficking, although the exact compartment that triggers this event seems to differ between strains and flavivirus species, perhaps indicating an optimal pH.⁸⁷¹ In the acidic environment, E protein dimers dissociate and undergo an irreversible conformational change to become fusogenic trimers.^{13,810} The fusion peptide, previously buried at the E homodimer interface, is exposed and inserts into the endosomal membrane (Video 25.1). The efficiency of fusion is influenced by the lipid composition of target membranes: cholesterol, oleic acid, and anionic lipids such as bis(monoacylglycerol)phosphate and phosphatidylserine enhance fusion, whereas lyophosphatidylcholine inhibits the process.^{812,813,950} Lipid composition can also influence the pH threshold of fusion.⁴²⁰ Following fusion, viral genomes are immediately accessible for translation.⁴²⁰

Genome Structure

As for other positive-strand RNA viruses, the genomes of flaviviruses are infectious.⁶⁶² Full-length infectious complementary DNA (cDNA) clones have been constructed for several species, allowing flavivirus biology to be dissected by reverse genetics.^{491,725,742} Flavivirus genomes consist of a single, positive-strand RNA of approximately 11 kilobases (kb) in length (sedimentation, 42S) with a 5' type 1 cap, m⁷GpppAmN^{151,901} (Fig. 25.4). The cap structure serves to stabilize the viral RNA, initiate translation, and subvert innate antiviral defenses.^{178,253} Unlike cellular mRNAs, flavivirus genomes lack a 3' polyadenylate tail.⁹⁰¹ Genomes encode a single long open reading frame (ORF, ~3,400 codons) flanked by 5' and 3' noncoding regions (NCRs) of ~100 nucleotides (nt) and 400 to 700 nt, respectively.⁵⁴⁴ (Fig. 25.4).

The sequence of the 5' NCR is not well conserved between flaviviruses, although common secondary structural elements have been identified, including a bifurcating 5' stem-loop (5' SL). These structures influence viral genome translation, as antisense oligonucleotides complementary to the 5' SL abolish DENV translation and replication, and second-site mutations in this region compensate for replication defects caused by reduced viral cap methylation. In addition, 5' SL likely acts as a promoter to initiate RNA replication by binding the viral NS5 polymerase/methyltransferase protein.^{196,236,237,506} Consistent with this, deletions within the 5' NCR cause severe defects in DENV-4 replication, but not viral translation.¹¹³ Interestingly, one of the viable mutants exhibited a limited host-range growth phenotype, suggesting that host-specific factors interact with either the 5' NCR or the complementary 3' end of the negative strand. Indeed, several human proteins, including La and TIAR, can bind to the 3' end of negative-strand RNA.^{472,778,938} WNV replication is inhibited in a TIAR-knockout cell line,⁴⁷² and mutagenesis of the TIA-1/TIAR binding sites suggests a role in initiating positive-strand RNA synthesis.²¹⁷

FIGURE 25.4. Flavivirus genome structure and protein expression. **A:** Genome structure and RNA elements. The viral genome is depicted with the open reading frame (ORF), the 5' cap, and the 5' and 3' noncoding regions (NCR) indicated. Functionally significant RNA structures within the viral genome are indicated. (See the text for further details.) **B:** Polyprotein processing and cleavage products. Boxes below the genome indicate precursors and mature proteins generated by the proteolytic processing cascade. Structural proteins are colored purple, while nonstructural (NS) proteins are white or shaded according to their enzymatic subunits, as indicated. Cleavage sites for host signalase (♦), the viral serine protease (downward arrow), furin or related protease (triangle), or unknown proteases (?) are indicated. **C:** Polyprotein membrane topology. The proposed membrane orientation of the flavivirus proteins is shown. The proteins are approximately to scale (areas are proportional to the number of amino acids) and arranged in order (left to right) of their appearance in the polyprotein.

The organization of the 3' NCR differs between mosquito-borne viruses, tick-borne viruses, and viruses with no known vector. Nevertheless, conserved regions, sequence duplications, and predicted RNA secondary structures are shared among the groups (Fig. 25.4). The greatest structural similarity is a long (90 to 120 nt) 3' stem-loop (3' SL) that differs in primary sequence between mosquito-borne and tick-borne flaviviruses.²⁹⁶ Mutational analysis of DENV-2 and WNV revealed essential virus-specific and host-specific functional regions within the 3' SL.^{216,856,947,953} The 3' SL enhances translation of reporter mRNAs containing the DENV 3' NCR,^{140,335} while DENV-2 translation and replication were inhibited by a corresponding antisense oligonucleotide.³³⁶ The 3' SL also interacts with several important proteins, including the viral NS2A, NS3, and NS5 proteins^{129,175,535} and translation elongation factor 1A (EF1A).^{75,183,185} These results are intriguing, because EF1A, and its prokaryotic homolog EF-Tu, contribute to the replication of other positive-strand RNA viruses.^{81,314,379,951} In addition, the human La autoantigen,^{185,262,875} polypyrimidine tract binding (PTB) protein,¹⁸⁵ and murine Mov34 protein⁸²² were found to bind 3' SL of DENV-4 and JEV, although the functional relevance of these interactions is presently unknown.

Upstream of the 3' SL lie conserved sequence repeats (CS1, CS2, CS3, RCS2, and RCS3), secondary structures, and putative pseudoknots.²⁹⁶ Some of these structures confer resistance to the cellular 5'-3' exoribonuclease Xrn-1,^{252,785} suggesting that this region of the genome forms a compact structure.

Flavivirus genomes can be circularized through long-distance base pairing between elements located near the 5' and 3' ends. In mosquito-borne flaviviruses, these interactions are mediated by the 5' UAR (upstream of AUG region), 5' DAR (downstream of AUG region), and 5' CS (conserved sequence), which base-pair with the 3' UAR, 3' DAR, and 3' CS1 regions, respectively, located more than 10 kb downstream at the base of the 3' SL.³⁵⁴ A distinct set of long-distance interactions circularizes the genomes of tick-borne flaviviruses.^{394,410} These long-range base pairs are important for RNA replication, presumably by bringing the 5' SL-bound NS5 protein in proximity to the 3' site of minus-strand initiation.^{18,96,167,196,236,237,248,354,394,410,940} It should be noted that genome circularization requires the melting of local secondary structures within the 5' and 3' ends and leads to the occlusion of the translation start site. Thus, large-scale conformation changes within the flavivirus genome may regulate the switch from translation to RNA replication.

Translation and Proteolytic Processing

The efficiency of genome translation is a primary determinant of flavivirus infectivity.²⁰⁹ The viruses therefore use several mechanisms to ensure translational competence, including specialized structures within the 5′ and 3′ NCRs. Translation is cap dependent, and 2′-O methylation of the 5′ cap helps to overcome innate antiviral defenses that down-regulate translation in infected cells.¹⁷⁸ While translation initiates via ribosomal scanning, many mosquito-borne flaviviruses lack a canonical Kozak initiation motif and contain several AUG codons near the correct start site. To help ensure proper AUG selection, DENV uses a small RNA stem-loop embedded within the C gene to induce ribosomal pausing over the authentic initiation codon.¹⁵⁵

Translation of the single, long ORF produces a large polyprotein that is co- and posttranslationally cleaved into at least 10 proteins (Fig. 25.4B). The N-terminal region of the polyprotein encodes the structural proteins (C-prM-E), which are followed by the NS proteins (NS1-NS2A-NS2B-NS3-NS4A-2K-NS4B-NS5).^{119,120,726} Host signal peptidase is responsible for cleavages between C/prM, prM/E, E/NS1, and 2K-NS4B. A virus-encoded serine protease, NS2B-3, processes at the NS2A/NS2B, NS2B/NS3, NS3/NS4A, NS4A/2K, and NS4B/NS5 junctions. The enzyme responsible for NS1-2A cleavage is presently unknown. The expected topology of the flavivirus polyprotein is depicted in Figure 25.4C.

Features of the Structural Proteins

C Protein

Capsid (C) protein is a highly basic protein of ~11 kD. The nascent protein contains a C-terminal hydrophobic tail that serves as a signal peptide for ER translocation of prM. This anchor is cleaved in two steps, first by the viral NS2B-3 protease and then by signal peptidase.⁵⁰³ Mature C protein folds into a compact dimer with each monomer containing four α -helices^{193,372,529} (Fig. 25.5). The N-terminal region of the

positively charged surface: RNA interaction?

hydrophobic surface: membrane interaction?

FIGURE 25.5. Flavivirus C protein structure. The WNV-KUN C protein is shown as a ribbon diagram with the protein surface rendered transparent, from PDB accession number 1SFK.¹⁹³ One monomer of the dimer is colored blue, the other green.

protein remains unstructured and, along with charged residues at the C-terminus, is thought to be involved in RNA binding.³⁹⁸ An internal hydrophobic region mediates membrane association of C.⁵²⁹

Overall, flavivirus C proteins demonstrate remarkable functional flexibility, with tolerance for large deletions. YFV C retains its ability to package RNA even after deletion of nearly 40 residues from the N-terminus or 27 residues of the C-terminus; internal deletions of the hydrophobic sequence are less tolerated.⁶⁵⁴ The TBEV C protein can accept deletions of up to 16 amino acids from the central hydrophobic helix, albeit with increased production of empty particles.⁴⁰⁹ Mutants containing larger deletions are not viable but can be rescued by second-site changes that increase the hydrophobicity of downstream sequences.⁴¹¹ WNV tolerates small deletions in hydrophobic helix $\alpha 2$ to various degrees. Remarkably, infectivity of the deleted genomes was improved by even larger deletions—up to one-third of the C protein sequence—encompassing all of helix $\alpha 3$.⁷⁶⁵ This results in the loss of a hydrophilic stretch, again suggesting the importance of hydrophobicity. It is not yet clear how C protein dimers are organized within the apparently disordered nucleocapsids, but interaction with RNA or DNA can induce isolated C protein dimers to assemble into nucleocapsid-like particles *in vitro*.³⁹⁹

Membrane Glycoprotein prM

The glycoprotein precursor of M, prM (~26 kD), is translocated into the ER via a signal sequence provided by the hydrophobic tail of C. Signal peptidase cleavage is delayed, however, until the viral serine protease cleaves on the cytosolic side of the membrane to generate the mature form of C.^{19,503,924} This delay seems to result from the combination of a fairly short (14 to 22 amino acids) signal sequence, suboptimal residues at the signalase cleavage site, and residues in downstream regions of prM^{504,815} and E protein.⁵¹¹ Interestingly, uncoupling signal peptidase cleavage from NS2B-3 processing leads to increased production of empty virus particles.^{459,504,505} Coordinated cleavage therefore serves to delay structural protein processing until the viral serine protease has accumulated and replication is under way, which may limit the release of immunogenic but noninfectious SVPs early in infection.

The N-terminal region of prM contains one to three N-linked glycosylation sites¹²² and six conserved cysteine residues, all of which are disulfide linked.⁶³³ The prM protein folds rapidly and assists in the proper folding of E.^{415,511} The C-terminal transmembrane (TM) domains of prM and E act as ER retention signals and may assist in their heterodimerization.^{486,641,643} A major function of prM is to prevent E from undergoing acid-catalyzed rearrangement and fusion during transit of the virions through the secretory pathway.^{302,322} The crystal structure of DENV prM in complex with E has recently been solved and demonstrates how this function is performed.⁴⁷¹ The pr domain is a unique fold consisting of seven β strands, with the previously identified disulfide bonds stabilizing the structure. In immature particles, the pr region sits at the tip of the E protein, forming the pr-E spike and shielding the fusion peptide from the cellular environment (Fig. 25.6A). prM is not accessible to furin cleavage in these particles due to steric hindrance.⁴⁷¹ The acidity of the *trans*-Golgi compartment induces a global rearrangement that exposes the furin cleavage site.⁹⁴⁶ After cleavage, the pr peptide does not immediately

FIGURE 25.6. Flavivirus glycoprotein structures. **A:** The structure of a dengue virus 2 (DENV-2) E glycoprotein dimer is represented in this ribbon diagram, as viewed perpendicular (**top**) or laterally (**bottom**) with respect to the lipid bilayer. One E monomer is colored red (domain I), yellow (domain II), and blue gray (domain III). The amino acid side chains of the fusion peptide are shown (orange). Rendered from PDB 1OAN.⁵⁹¹ In the **bottom panel**, the low pH conformation of the DENV-2 pr protein from PDB 3CSX⁴⁷¹ was modeled onto the structure of 1OAN. **B:** tick-borne encephalitis virus (TBEV) E protein trimers in their postfusion form, colored as in **A**. Rendered from PDB 1URZ.⁹⁸

disassociate from the virus particle.⁸⁰² Exposure to the neutral pH of the extracellular space is required to release pr and reveal the fusion-competent mature virion. This delay prevents the cleaved particles from undergoing premature membrane fusion within the Golgi.

Envelope Glycoprotein

E protein (~53 kD) is the major protein on the surface of flavivirus virions. E is synthesized as a type I membrane protein containing 12 conserved cysteines that form disulfide bonds⁶³⁴; in some viral species E is N-glycosylated.^{123,909} Proper folding, stabilization in low pH, and secretion of E depends on co-expression with prM.^{415,511} E is a class II fusion protein that mediates both receptor binding and membrane fusion.

Atomic resolution structures of E proteins from several flaviviruses have been solved in pre- and postfusion conformations.^{98,382,591–592,593,625,635,722,958} In its prefusion form, E folds into an elongated structure rich in β -sheets and forming head-to-tail homodimers that lie parallel to the virus envelope.^{591,722} Each E protein is composed of three domains: DI, which forms an eight-stranded β -barrel; DII, a long, finger-like domain that projects along the virus surface; and DIII, which maintains an immunoglobulin-like fold (Fig. 25.6A). The fusion peptide¹² is located at the tip of DII and remains covered by the pr peptide or buried in a hydrophobic pocket formed by DI and DIII of the partner monomer until triggered to insert into the target cell membrane.⁷²² DIII projects slightly from the virion surface and is thought to be involved in receptor binding; it is a major target of neutralizing antibodies.¹⁴⁵ Between the ectodomain of E and the membrane is a short but functionally important

stem region composed of two α -helices that lie parallel to the plane of the membrane.^{15,956}

On exposure to low pH, E protein dimers dissociate into monomeric subunits, which then form fusogenic trimers.^{13,810,811} Interestingly, the WNV E protein crystal structure shows an array of perpendicular monomers, suggesting a mechanism for E protein rotation without exposing the fusion loop.^{635,814} Crystal structures of postfusion E show the protein folded back onto itself, bringing the N-terminal fusion peptide, with its associated cellular membrane, into proximity with C-terminal TM domain, which is still integrated in the viral membrane^{98,592} (Fig. 25.6B). To accomplish this, DIII must rotate and fold back more than 30 Å in relation to DI. Indeed, neutralizing antibodies against DIII can inhibit a postattachment step of viral entry,⁶³⁶ and a soluble, recombinant form of DIII is a potent dominant-negative inhibitor of fusion.⁴⁷⁸ In addition, DII rotates relative to DI,^{98,592} with similar displacement of DII seen in crystals of native E protein grown in the presence of the detergent β -octylglucoside.^{591,958} Residues that influence the pH threshold for membrane fusion surround the DI/DII pocket.⁵⁹¹ Protonation of conserved histidines at the interface of DI and DIII also contribute to E domain rearrangements in TBEV RSPs.²⁴⁹ Mutagenesis studies of WNV, however, failed to identify histidine residues that entirely control the switch.⁶²⁹

Features of the Nonstructural Proteins

NS1 Glycoprotein

The NS1 glycoprotein (~46 kD) is translocated into the ER during synthesis and processed at its N-terminus by host signal

peptidase. The C-terminus of NS1 arises through NS1–2A cleavage by an unknown ER-resident host enzyme, which requires the eight C-terminal residues of NS1 and greater than 140 amino acids of NS2A.^{227,228,340} In addition, JEV expresses an elongated form of NS1, termed NS1', which arises through a ribosomal –1 frameshifting event.^{80,238,547,565}

NS1 contains two or three N-linked glycosylation sites and 12 conserved cysteines that form disulfide bonds.^{79,461,547,797,884} Around 30 minutes after synthesis, NS1 simultaneously forms highly stable homodimers and acquires an affinity for membranes.^{910,911} As NS1 lacks a known membrane interaction domain, the nature of its membrane association remains unclear. One possibility is that dimerization creates a hydrophobic surface for peripheral membrane binding. Alternatively, it has been reported that DENV-2 NS1 exhibits properties of a glycosylphosphatidylinositol (GPI)-anchored protein, although this mechanism seems inconsistent with the C-terminal peptide sequence of this protein.⁹⁰²

NS1 is retained within a secretory-derived compartment, expressed on the surface of infected cells, and efficiently secreted from mammalian, but not insect, cells.^{491,816} The relative distribution of NS1 within these compartments is regulated through an unknown mechanism involving a short, N-terminal region of the protein.⁹⁴² The secreted form of NS1 accumulates to high levels in human sera and tissues and can be used to diagnose flavivirus infections at an early stage.^{8,147,531} Secreted NS1 forms soluble, hexameric lipoprotein particles of ~10 nm that appear as three dimers held together in a barrel configuration.^{172,239,304} The secreted form of NS1 can bind to uninfected cells by interaction with sulfated glycosaminoglycans³³ and can be internalized and trafficked to late endosomes, where it accumulates.⁹ The function of endocytosed NS1 is not yet clear, but it may enhance subsequent infection with the homologous virus.⁹

The intracellular form of NS1 localizes to sites of viral RNA synthesis and plays an essential role in genome replication.^{533,904} Mutations in NS1 can lead to dramatic defects in RNA replication and infectious virus production.^{170,619,620} *trans*-Complementation studies revealed that NS1 functions at an early stage in RNA replication through a genetic interaction with NS4A.^{395,396,490,492}

The extracellular forms of NS1 are highly antigenic and induce a strong humoral response. Secreted NS1 was originally characterized as a soluble, complement-fixing antigen present in the serum and tissues of DENV-infected animals. Antibodies that recognize cell surface-bound NS1 can direct complement-mediated lysis of infected cells and protect animals from lethal disease; other NS1-specific antibodies are protective in a complement-independent manner.^{148,149} Antibody-mediated cross-linking of cell surface NS1 can also induce signaling cascades in DENV-2-infected cells, and it has been proposed that NS1 may contribute to pathogenesis by inducing antibodies that cross-react with human proteins. Despite the strong link between NS1-specific humoral responses and complement fixation, recent evidence indicates that WNV NS1 can inhibit the alternative pathway of complement activation by binding to and inhibiting the serum protein factor H. Furthermore, DENV, WNV, and YFV NS1 inhibit the classical pathway of complement fixation by binding to and increasing the turnover of complement factor C4. NS1 clearly plays an important role in flavivirus-specific humoral responses.

NS2A and NS2B Proteins

NS2A is a relatively small (~22 kD) hydrophobic protein. Its N-terminus is generated by an unidentified ER-resident host enzyme,²²⁸ whereas the C-terminus is generated by NS2B-3 cleavage in the cytoplasm. Thus, NS2A is membrane spanning, although the precise topology of the protein is unknown. In addition, the YFV serine protease can cleave at an internal site in NS2A to generate a C-terminally truncated form, NS2A α .^{123,630} Interestingly, mutations at the YFV NS2A α cleavage site block virus particle production and can be suppressed by a second mutation on the surface of the NS3 helicase domain.⁴³⁴ Mutations in KUNV NS2A similarly block virus assembly, while the protein also localizes to subcellular sites of RNA replication and interacts with replicase components NS3, NS5, and the 3' NCR of genome RNA. The involvement of NS proteins, in particular the NS2–3 region, in replication and infectious virus assembly appears to be an emerging theme for all three genera of the family *Flaviviridae*.

DENV-2 and WNV NS2A can also inhibit interferon (IFN) signaling, as evidenced by specific mutations in the protein that diminish this inhibitory activity and attenuate virulence in mice.^{498,500,613} Interestingly, these mutations are cell culture adaptive and enhance the ability of KUNV replicons to establish persistence in IFN-competent cell lines. Remarkably, NS2A of the tick-borne flavivirus Langat does not share this property, which appears to be carried out instead by NS5.⁶⁶

NS2B is also a small (~14 kD) membrane-associated protein.¹⁵⁴ NS2B forms a stable complex with NS3, serves to anchor this complex to cellular membranes, and acts as an essential co-factor for the NS2B-3 serine protease.²²⁹ The co-factor activity lies in a central peptide that intercalates within the fold of the serine protease domain.^{31,125,221}

NS3 Protein

NS3 is a large (~70 kD) multifunctional protein, encoding enzymatic activities required for polypeptide processing and RNA replication. The N-terminal third of the protein is the catalytic domain of the NS2B-3 serine protease,^{50,124,279} which has specificity for substrates containing adjacent basic residues at the NS2A/NS2B, NS2B/NS3, NS3/NS4A, and NS4B/NS5 junctions.¹²² In addition, this protease generates the C-termini of mature capsid protein^{19,924} and NS4A⁴⁸¹ and can cleave at internal sites within NS2A and NS3.

Soluble, recombinant forms of the NS2B-3 serine protease domain have been purified and crystallized for x-ray diffraction.^{125,221,733} These structures show that the co-factor region of NS2B contributes a β -strand to complete the chymotrypsin-like fold of the protease (Fig. 25.7A), similar to hepatitis C virus (HCV) NS3-4A. The C-terminal region of the NS2B co-factor can adopt multiple conformations that may alternately help to form the substrate-binding pocket or project outward from the protease fold; it is not yet clear whether these structural rearrangements are biologically significant.

As for other members of the *Flaviviridae*, the C-terminal region of NS3 encodes a supergroup 2 RNA helicase–nucleoside triphosphatase (NTPase).²⁸⁰ NS3 demonstrates RNA-stimulated NTPase and RNA unwinding activities^{890,899} and mutagenesis of the active site residues confirmed that these activities are essential for viral replication.⁵⁴⁹ This region of NS3 also exhibits RNA triphosphatase (RTPase) activity, proposed to dephosphorylate the 5' end of the genome before cap addition.⁹⁰⁰ Recent

Active-site residues are shown in red. Rendered from PDB number 2FP7.²²¹ **B:** Structure of the dengue fever 4 (DENV-4) NS3 helicase domain with (left) or without (right) bound RNA substrate (colored spheres) and adenosine triphosphate (ATP) analog (black). Note the adenosine triphosphatase (ATPase) active site (red) becomes structured at the interface of domain I (cyan) and domain II (purple) upon RNA binding. The RNA is bound within a cleft formed by the first two domains and domain III (gold). Rendered from PDB numbers 2JLQ and 2JLV.⁵²³ **C:** Structural interdomain flexibility within full-length NS3. Shown are two conformations of full-length DENV-4 NS3 (PDBs 2VBC⁵²² and 2WHX,⁵²¹ respectively), Murray Valley encephalitis virus (MVEV) (PDB 2WV9⁹¹), and hepatitis C virus (HCV) (PDB 1CU1⁹³⁰). Shown is a structural alignment of the helicases, with molecular surfaces colored as in **A** and **B** and the protease-helicase linker in yellow.

studies show that RTPase is dependent on the Walker B motif in the helicase–NTPase catalytic core for phosphodiester bond hydrolysis.^{41,58} Thus, all three nucleic acid–modifying activities of NS3 rely on a common active center. In addition to its roles in RNA replication, the helicase domain of NS3 has been implicated in virus assembly,^{434,655} a role that is separable from the known enzymatic activities and can function *in trans*.⁶⁵⁵

Crystal structures of isolated DENV and YFV NS3 helicase domains show three subdomains, two structurally conserved RecA-like domains that are involved in NTP hydrolysis, and a unique C-terminal domain that may be involved in virus-specific RNA and protein recognition.^{523,916,921} Co-crystallization of the DENV helicase with or without RNA substrates and nucleoside analogs revealed the structural basis for RNA-stimulated adenosine triphosphatase (ATPase) activity and substrate unwinding⁵²³ (Fig. 25.7B). The structures of full-length DENV and MVEV NS3 have recently been solved in complex with their corresponding NS2B co-factors.^{31,521,522} In these structures, the serine protease and helicase regions largely retain their domain folds, forming an elongated binary complex. However, the relative orientation of the domains differ, and greatly differ from the orientation of the related domains in HCV NS3, implying that the flexible linker region may play an important role in coordinating enzyme activities

(Fig. 25.7C). The DENV structure also revealed that the serine protease domain can contribute to RNA helicase activity.⁵²²

Truncated forms of NS3, which result from alternative serine protease cleavage events in the helicase domain, have been observed *in vitro* and *in vivo*. The role of these cleavages is unclear, although it is possible that the products could have a distinct function. In this regard, replication defects caused by deletions in the KUNV helicase domain can be complemented *in trans*, while deletions in the serine protease domain cannot be complemented.^{374,396,499}

Finally, the NS3 proteins of Langat, DENV-2, and WNV have been shown to induce apoptosis, in some cases through activation of caspase-8.^{691,704,776} Flaviviruses are often cytopathic in mammalian cells, although whether this is the normal pathway for cell killing requires further study. The DENV NS2B-3 serine protease can also down-regulate the activation of type I IFN in human dendritic cells, although the relevant protease substrate(s) have not been identified.⁷³⁶

The NS4A and NS4B Proteins

NS4A and NS4B are small (16 kD and 27 kD, respectively) hydrophobic proteins. NS4A has been implicated in RNA replication through a genetic interaction with NS1⁴⁹⁰ and co-localization with replication complexes.⁵³⁵ Similar to the

coordinated processing of C protein, signal peptidase cleavage at the 2K/NS4B junction requires prior cleavage by the NS2B-3 serine protease at a site just upstream of the 2K internal signal peptide.^{481,690} Overexpression studies showed that NS4A can induce membrane rearrangements and/or formation of autophagosomes, and that regulated NS4A/2K/4B cleavage is necessary for this activity.^{560,586,738} Mutations in NS4A and 2K have been found to confer resistance to a potent inhibitor of flavivirus RNA replication and to overcome superinfection exclusion, further implicating this region in RNA replication.^{966,967}

NS4B is a polytopic membrane protein that co-localizes with NS3 at the presumed sites of RNA replication.^{481,587} NS4B is posttranslationally modified to a form that migrates faster on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE),^{123,690} although the identity and function of this modification remain to be determined. Similar to NS2A, DENV NS4A and NS4B can block type I IFN signaling.⁶¹³ NS4B has the strongest antagonistic effect, which requires either proper processing of the NS4A–NS4B polypeptide or expression of NS4B with an N-terminal signal peptide.⁶¹² Similarly, WNV NS4A and NS4B block IFN signaling by inducing an unfolded protein response in the ER, which can down-regulate Jak-STAT signaling.²⁰

NS5 Protein

NS5 is a large (103 kD), highly conserved, multifunctional phosphoprotein with RNA capping and RdRP activities encoded within its N- and C-terminal regions, respectively.¹⁸¹ Formation of a type 1 RNA cap involves multiple steps, including (a) removal of one phosphate from a 5' triphosphorylated RNA substrate by an RTPase, (b) addition of a 5'-5' guanosine cap (from guanosine triphosphate [GTP]) by a guanylyltransferase, (c) N7-methylation of the guanylyl cap by a methyltransferase (MTase), and (d) 2'-O methylation of the second residue by the same or another MTase. As mentioned earlier, the NS3 helicase–NTPase exhibits RTPase activity, which suggests that NS3

and NS5 function together during RNA capping.^{41,900} The flavivirus guanylyltransferase proved to be elusive for many years, although recent evidence indicates that the N-terminal domain of NS5 is capable of performing this reaction.³⁶¹ Finally, the N-terminal region of NS5 encodes conserved MTase motifs and is capable of performing both N7 and 2'-O methylation in a coordinated fashion.^{211,417,713} The structure of the NS5 capping domain has been solved by x-ray crystallography under a variety of conditions, revealing high-resolution structures of these reaction pathways^{181,211,266,931} (Fig. 25.8A). Mutagenesis of the NS5 capping domain showed that the methylation events are separable and that N7 methylation is required for viral translation and replication, while 2'-O methylation allows the virus to avoid innate antiviral defenses.^{178,195,427,964} Interestingly, cellular casein kinase 1 can phosphorylate YFV NS5 *in vitro* at a serine residue near the methyltransferase active site, which inhibits 2'-O methylation.^{67,68} While inhibitors of this kinase affect YFV replication, it is not known if this site is phosphorylated *in vivo*.

The C-terminal domain of NS5 contains conserved RdRP motifs^{417,726} and structurally resembles other RNA polymerases, forming a “right hand” structure with palm, fingers, and thumb subdomains^{181,543,932} (Fig. 25.8B). NS5 RNA polymerase activity has been confirmed with purified, recombinant protein^{1,181,305,826}; mutagenesis of the polymerase active site; and supplying the activity *in trans* from a KUNV replicon. The major product of *in vitro* RdRP reactions is often a self-primed copy-back RNA. However, NS5 is capable of initiating RNA synthesis *de novo*,^{1,632,948} which likely reflects the authentic mechanism in infected cells. NS5 forms a complex with NS3^{371,389} and stimulates NS3 NTPase and RTPase activities.^{175,939} Cross-linking studies have shown that both proteins bind to the 3' SL of the viral genome.¹²⁹ Along with genome circularization, this may serve to initiate minus-strand synthesis by 5' SL-bound NS5.^{196,237,354,940}

WNV and DENV-2 NS5 have been shown to localize at sites of viral RNA synthesis,^{534,898} although this has been

FIGURE 25.8. Viral NS5 and NS5B proteins. **A:** The yellow fever virus (YFV) capping domain is shown, with bound methyl donor S-adenosyl-L-homocysteine (SAH) and guanosine triphosphate (GTP). Rendered from PDB number 3EVC.²⁶⁶ **B:** A structural comparison of RNA-dependent RNA polymerases (RdRP) domains across the *Flaviviridae*. The dengue virus 3 (DENV-3) RdRP domain is shown, with the canonical finger (cyan), palm (pink), and thumb (purple) domains indicated. A flavivirus-specific interdomain insertion is shown in green. This structure shows the binding site of a GTP analog, which is important for activating *de novo* RNA synthesis. GTP-binding residues are blue, RdRP active-site residues are red, and a catalytic Mg²⁺ ion is shown as a green sphere. Structural Zn²⁺ ions are shown in black. This model is a composite structure, rendered from PDB numbers 2J7U and 2J7W.⁹³² The hepatitis C virus (HCV) NS5B RdRP is shown with bound template RNA; the HCV-specific C-terminal extension is shown in yellow. Rendered from PDB number 1NB7.⁶³⁷ The bovine viral diarrhea virus 1 (BVDV-1) NS5B RdRP is shown modeled in the GTP-bound state by rendering PDB number 2JCQ and the GTP analog from 2J7W. The pestivirus-specific N-terminal extension is shown in green.

difficult to show for other viruses. Biochemical studies indicate that only a small fraction of NS5 co-fractionates with replicase activity,^{298,868} and the protein is frequently localized to the nucleus of flavivirus-infected cells.^{181,389} These results suggest that NS5 may play additional roles, other than in RNA replication, in the virus life cycle. In this regard, DENV-2 NS5 induces interleukin-8 (IL-8) transcription and secretion, which may enhance viral spread or disease by recruiting inflammatory cells to the site of infection.⁵⁶² In addition, NS5 has been shown to block the Jak-STAT pathway of IFN signaling.^{66,181}

RNA Replication

The flavivirus NS proteins presumably recruit the viral genome out of translation and into a replication complex. Replication begins with the synthesis of a genome-length minus-strand RNA, which then serves as a template for new plus-strand genomes. Minus-strand RNA has been detected as early as 3 hours after infection.⁴⁹² Viral RNA synthesis is asymmetric, with approximately 10-fold more positive strands accumulating compared to minus strands.^{152,620} Flavivirus replication can be followed by metabolic labeling of virus-specific RNA in the presence of actinomycin D, an inhibitor of DNA-dependent RNA polymerases. Three major species of labeled flavivirus RNA have been described, including the plus-strand genome, a double-stranded replicative form (RF), and a heterogeneous population of replicative intermediates (RIs) that most likely represent duplex regions and recently synthesized RNAs displaced by nascent strands undergoing elongation.^{146,152} Pulse-chase analyses indicate that RF and RI are precursors to genome RNA,^{146,152} indicating semiconservative and asymmetric replication.¹⁴⁶

In addition to genome-length plus- and minus-strand products of RNA replication, 0.2- to 0.6-kb subgenomic flavivirus RNAs (sfRNAs) are produced in infected cells.^{485,762,869}

sfRNAs are co-linear with the 3' end of the genome and are produced through incomplete degradation of the genome by the cellular 5'-3' exoribonuclease Xrn1.^{678,785} The Xrn1 resistance of this region is due to conserved secondary structures and pseudoknots located within the 3' NCR.^{252,785} While controversy exists over whether sfRNAs are needed for efficient RNA replication, a WNV mutant that does not produce sfRNAs is less cytopathic in cell culture and less pathogenic in mice.^{252,678,785} Interestingly, supplying sfRNA *in trans* restored WNV cytopathic effect in cell culture, suggesting that these small RNAs may have a specific but as yet unknown target.⁶⁷⁸

Membrane Reorganization and the Compartmentalization of Flavivirus Replication

Biochemical studies of flavivirus-infected cells show that replicase activity is concentrated in dense membrane fractions that are enriched for most viral NS proteins. Treatment with non-ionic detergents increases sensitivity to nucleases and proteases, indicating that the active replicase resides within a membrane-bound compartment. Consistent with this, ultrastructural changes in perinuclear membranes can be detected in flavivirus-infected cells.⁸⁹⁸ In general, the earliest event is the proliferation of ER membranes, followed by the appearance of smooth vesicular structures around the time of early logarithmic virus production. These structures, sometimes referred to as double-membrane vesicles or vesicle packets, are small clusters of ~90-nm vesicles within the lumen of the ER.^{898,904} They are frequently adjacent to ER-derived convoluted membranes, which can appear as randomly folded membranes or highly ordered "paracrystalline arrays".^{454,616,898} Electron tomography revealed that these vesicles are invaginations of the ER and retain connectivity to the cytosol through a neck-like pore, sometimes apposed to sites of virus assembly⁸⁹⁸ (Fig. 25.9).

FIGURE 25.9. Sites of dengue virus (DENV) RNA replication and virus particle assembly. The three tomographic slices, each ~2 nm thick, show DENV-induced vesicles (Ve) associated with the endoplasmic reticulum (ER) and nuclear envelope (NE). White arrowheads indicate necked connections between the Ve and ER membranes; black arrowheads indicate virus particles. To the right is a three-dimensional reconstruction of the membrane surfaces (tan) and virus particles (red). The white arrow indicates a putative site of virus budding. (Courtesy of Drs. Sonja Welsch and Ralf Bartenschlager. Adapted from Welsch S, Miller S, Romero-Brey I, et al. Composition and three-dimensional architecture of the dengue virus replication and assembly sites. *Cell Host Microbe* 2009;5:365–375, with permission from Elsevier.)

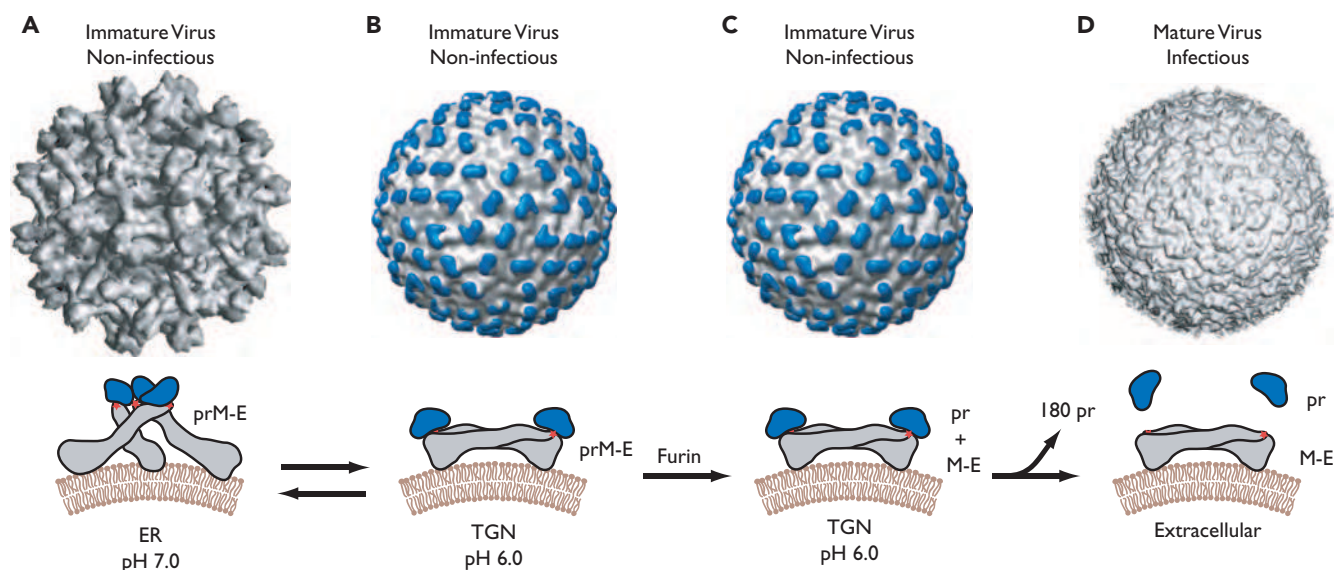

FIGURE 25.10. Flavivirus particle maturation. Nascent, noninfectious, immature particles undergo a pH-dependent conformational rearrangement of the viral glycoproteins E (gray) and precursor M (prM) (blue). Mature, infectious particles form upon furin cleavage of prM and release of the pr fragment. (Adapted from Perera R, Kuhn RJ. Structural proteomics of dengue virus. *Curr Opin Microbiol* 2008;11:369–377, with permission from Elsevier.)

Perinuclear vesicle packets have been confirmed as the sites of viral RNA synthesis by metabolic labeling of nascent RNA, *in situ* hybridization, and immunodetection of double-stranded RNA (dsRNA) (presumably RF and RI).

The pathways of flavivirus-induced membrane reorganization are currently being worked out. One important clue comes from the ability of DENV-2 NS3 to recruit the cellular fatty acid synthase to sites of replication, at least by late times of infection.³¹⁹ In addition, DENV induces autophagosome formation in infected cells,^{393,463,560,651} leading to turnover of triglycerides into free fatty acids, β -oxidation of lipids, and increased adenosine triphosphate (ATP) levels that promote virus replication.³²⁰

Assembly and Release of Particles from Flavivirus-Infected Cells

Similar to replication, early ultrastructural studies indicated that flavivirus morphogenesis occurs in close association with intracellular membranes.⁶¹⁵ The assembly process is thought to commence by association of C protein dimers with genomic RNA, followed by budding into ER membranes containing the E–prM glycoprotein complex. Recent electron tomography studies of DENV-infected cells have shown that replicate-containing vesicle packets and ER-associated sites of virus budding are part of one continuous network. Pores within the replication vesicles appear to release newly synthesized viral RNA directly adjacent to budding DENV particles.⁸⁹⁸ These findings suggest a potential mechanism for coupling of flavivirus replication and assembly.³⁹⁷ Interdependence of these processes is a common theme among RNA viruses and might serve to reduce the propagation of defective genomes. Coupling flavivirus replication and assembly may also explain the roles of NS2A and NS3 proteins in infectious virus assembly.^{434,465,497,655}

Following assembly, nascent virions are transported through the secretory pathway and released at the cell surface.⁵³⁶

It is during secretion that immature particles undergo acid-induced E–prM rearrangement and prM cleavage (Fig. 25.10). Additional virion maturation steps occur during egress, including glycan modification of prM and E (for some viruses) by trimming and terminal addition.^{123,169,309,547} This implies that virions move through an exocytosis pathway similar to that used for host cell surface glycoproteins. In addition to the secretory pathway machinery, other host factors have been implicated in flavivirus morphogenesis. Inhibitor and RNA interference studies implicate the Src family kinase c-Yes in WNV egress from the ER.³³³ A serine/threonine protein phosphatase inhibitor, I(2)(PP2A), has also been found to bind the WNV C protein, although its importance for infectivity was minimal.³⁵⁰

HEPATITIS C VIRUSES

Background and Classification

HCV was identified in 1989 through expression cloning of immunoreactive cDNA from the plasma of a chimpanzee infected with an etiologic agent known to cause non-A non-B viral hepatitis.¹⁴³ The virus currently infects more than 130 million people worldwide and remains a significant public health concern. HCV typically causes chronic hepatotropic infections, which can progress over decades to fibrosis, cirrhosis, and liver cancer. Based on difficulties in detecting HCV *in vivo*, the virus was originally thought to replicate poorly. Yet mathematical models of HCV dynamics indicate that a chronically infected patient produces approximately 10^{12} virions per day, with a virion half-life of only a few hours.⁶⁶⁶

Based on its evolutionary history, HCV is classified into seven genotypes, which differ from each other by more than 30% at the nucleotide level.^{614,788} Each genotype is further divided into numerous subtypes. HCV genotypes show differences in worldwide distribution, disease progression, and susceptibility to

treatment. In addition, intergenotypic and intersubtype recombinant HCV genomes have been described.⁷⁸⁸

While no HCV vaccine exists, advances in treatment have been made. Pegylated IFN- α and ribavirin—the standard of care for over a decade—have burdensome side effects and do not cure many of the patients treated. The most common HCV genotype, genotype 1, is also the most difficult to treat with this therapy.³³⁴ Recently, however, HCV-specific antiviral drugs—such as protease inhibitors—have begun to reach the clinic. While the new drugs must still be used in combination with IFN and ribavirin, first-generation protease inhibitors have almost doubled the chances of treatment success.

In addition to HCV, the genus *Hepacivirus* may contain a few related viruses that are awaiting taxonomic classification. An HCV-like virus was recently identified in domestic dogs with respiratory illness.³⁸⁸ This virus appears to be closely related to HCV and has been tentatively designated canine hepacivirus (CHV), although it has not been formally classified within this genus. In addition, GB virus B (see later) appears to be closely related to the hepaciviruses.

Experimental Systems

HCV research was limited for years by the lack of convenient laboratory culture systems and small animal models. However, many of these technical hurdles have been overcome in the past decade.

Shortly after the sequence of the HCV genome was fully elucidated, the first consensus cDNA clones were constructed. RNA transcripts from these cDNAs were shown to be infectious by direct intrahepatic inoculation into chimpanzees.^{412,925} Chimpanzee infectious clones have been used to show that all viral enzymes, the *p7* gene, and 3' NCR are essential for HCV replication *in vivo*.^{414,750,926} Furthermore, the ability to use genetically defined inocula to initiate clonal infections provided a useful tool to study virus evolution and immune responses.¹⁰⁶ Despite their demonstrated utility *in vivo*, however, these infectious transcripts failed to replicate after transfection into cultured cells.

Subgenomic HCV replicons were developed in 1999 and proved to be the first broadly useful system for studying HCV RNA replication in cell culture.⁵⁰⁹ Subgenomic replicons are bicistronic constructs in which the HCV internal ribosome entry site (IRES) drives expression of the neomycin resistance gene and the encephalomyocarditis virus (EMCV) IRES drives expression of the HCV NS proteins. Following RNA transfection into a human hepatoma line, Huh-7, the original genotype 1b (Con1 strain) replicon replicated to low levels.⁵⁰⁹ Cell culture-adaptive mutations were later found to increase RNA replication efficiency up to 10,000 times.⁷⁷ These mutations, many of which cluster in NS5A, are thought to increase RNA accumulation at the expense of infectious virus production, although their mechanisms of action are not well understood (reviewed in⁴³). In addition to Con1, subgenomic replicons have now been constructed for additional genotype 1b strains, as well as genotype 1a and 2a isolates.

Full-length genotype 1a and 1b genomes bearing adaptive mutations were shown to replicate in cell culture but did not produce infectious virus particles.^{78,355,676} The HCV pseudoparticle (HCVpp) system was therefore developed to examine the role of the viral glycoproteins in entry. HCVpp are defective retrovirus particles expressing a reporter gene and

displaying the HCV envelope proteins on their surface.^{46,201,343} Pseudoparticles undergo low-pH-mediated entry by using the known HCV entry factors and continue to be a valuable system to study entry in isolation from RNA replication. HCVpp differ from authentic particles, however, in their acid susceptibility³⁴³ and their assembly in a post-Golgi compartment rather than in the ER.⁷⁵¹

In 2005, production of authentic HCV in cell culture (HCVcc) was achieved for the first time. An HCV isolate from an unusual case of acute fulminant hepatitis in Japan (JFH-1) was found to replicate in culture without the need for adaptive mutations.³⁹² Remarkably, full-length JFH-1 also produced low levels of infectious virus.^{883,959} Infectious titers could be increased with passage or by engineering chimeric genomes based on a related genotype 2a strain, J6.^{487,675} A cell culture-adapted genotype 1a genome that produces infectious HCVcc has also been developed, albeit with lower infectivity.⁹³⁷

The chimpanzee remains the only animal model that reproduces clinical aspects of HCV infection, including a high rate of viral persistence and the development of HCV-specific innate and adaptive immune responses. Advances have been made, however, in generating small animal models for HCV infection. Immunodeficient mouse strains with liver injury can be repopulated with human hepatocytes and infected with HCV. Two commonly used liver injury models are the toxic urokinase plasminogen activator transgene (Alb-uPA mice)^{568,570} and a conditionally lethal fumaryl acetoacrylate hydrolase deficiency (FAH^{-/-} mice).⁷³ Recently, immunocompetent mice that express human HCV entry factors have been developed as a model for the early steps of infection.¹⁹⁸

Structure and Physical Properties of the Virion

HCV particles are enveloped and contain the viral proteins core (C), E1, and E2, as well as the genomic RNA. Virions are between 30 and 80 nm in diameter.^{88,317,949} For a virus of this size, HCV exhibits an unusually low and heterogeneous buoyant density. In highly infectious acute-phase chimpanzee serum, HCV-specific RNA is detected in fractions with densities ranging from 1.03 to 1.10 g/mL.^{87,331} The particle density is inversely correlated with infectivity, with low-density virions being more infectious than high-density particles. Similar to serum-derived virus, the peak of HCVcc RNA has a buoyant density of approximately 1.15 g/mL,^{116,487,883,937,959} whereas the peak infectivity is near 1.10 g/mL.^{116,487,959} Passage of cell culture-grown virus in animals⁴⁸⁸ or primary hepatocyte cultures⁶⁸² increases the proportion of low-density, high-infectivity virus, highlighting the impact of host cell environment on virion composition.

The high density observed for noninfectious particles may come from immunoglobulin binding to the virus and/or represent nonenveloped nucleocapsids.²³ The low buoyant density of infectious HCV appears to reflect the ability of the virus to interact with serum lipoproteins.^{22,631,692,855} The lipidome of HCV particles is very similar to low-density lipoproteins (LDLs) and very-low-density lipoproteins (VLDLs), including an enrichment of cholesteryl esters.⁵⁶⁹ Immunoprecipitation and immunogold-electron microscopy (EM) studies have detected apolipoprotein (Apo) AI,⁴¹⁶ ApoB,^{416,631,855} ApoC1,⁵⁷² and ApoE⁶³¹ in association with serum-derived HCV. Apolipoprotein E and ApoC1 are also associated with HCVcc,^{126,569,572} but ApoB is generally lacking, leading to controversy about

FIGURE 25.11. Hepatitis C virus (HCV) particles produced in cell culture. **A:** Virus particles were purified and negative stained with uranyl acetate. **B:** A representative virus particle after extraction with 0.2% NP-40 and negative staining. **C:** A representative enveloped virus particle as imaged through cryoelectron microscopy. (Adapted from Gastaminza P, Dryden KA, Boyd B, et al. Ultrastructural and biophysical characterization of hepatitis C virus particles produced in cell culture. *J Virol* 2010;84:10999–11009, with permission of the American Society for Microbiology Press.)

its functional importance (reviewed in⁴⁴). The propensity of HCV to interact closely with lipids has led to the hypothesis that at least a portion of circulating virus is internalized in host lipoproteins to form a “lipoviral” particle,²² which may provide camouflage for the virus to escape neutralizing antibodies.

Although unambiguous visualization of HCV from patient samples remains a challenge, negative stain and cryoelectron microscopy studies have started to reveal structural features of HCV grown in cell culture^{264,569,883} (Fig. 25.11). One recent study detected two predominant classes of HCV particles, each making up approximately half of the preparation. The first were spherical, pleomorphic particles, ~55 nm in diameter, containing a lipid bilayer and an electron-dense core (Fig. 25.11C). These particles, which are presumably infectious HCV, were enriched in low-density fractions and had a relatively smooth, featureless surface that reacted with E2- and ApoE-specific antibodies. The second class of particles, electron-dense structures ~45 nm in diameter, is presumed to be naked nucleocapsids. This class was enriched in high-density, low-infectivity fractions and lacked a membrane or visible surface projections. Similar particles were seen after detergent treatment of infectious virus, which is expected to remove the viral envelope.²⁶⁴ Unfortunately, the reconstruction of high-resolution models of the virus particle is currently limited by particle heterogeneity, relatively low yields, and lack of symmetry in both classes of HCV particles.

Binding and Entry

HCV infects target hepatocytes through a multistep process that involves several cell surface molecules. Virus particles initially attach to glycosaminoglycans^{45,268} and possibly the LDL receptor (LDL-R),^{4,598} which may interact with virion-associated ApoB and ApoE. Following attachment, virus particles employ four specific entry factors to mediate uptake: scavenger receptor class B type I (SR-BI, aka SCARBI),⁷⁵⁸ CD81,⁶⁷⁹ claudin 1 (CLDN1),²²⁴ and occludin (OCLN).⁶⁸¹

SR-BI, which is highly expressed on hepatocytes, plays important physiologic roles in the selective uptake of cholesterol and cholesteryl esters from lipoproteins. SR-BI can interact with the E2 hypervariable region 1 (HVR1),⁷⁵⁸ and

its overexpression enhances virion binding to CHO cells,²²⁴ suggesting a role for SR-BI in primary attachment. Blocking antibody studies have both supported a role for SR-BI in binding,¹²¹ as well as shown the importance of SR-BI at a post-binding step that is closely linked to CD81.^{386,952} Antibodies directed at E2 HVR1 similarly block a postattachment step of HCV entry.⁸⁷⁸ The physiologic SR-BI binding partner, PDZK1, is also important for entry.²²⁵ Perhaps because the lipoviral particle shares commonalities with the natural ligands of SR-BI, various lipoproteins modulate HCV infectivity. Specifically, high-density lipoproteins (HDLs) can enhance HCV fusion in a manner dependent on SR-BI lipid transfer, ApoCI, and the E2 HVR1.^{47,199,571,880} In contrast, oxidized LDL,⁸⁸² VLDL,⁵⁴² and serum amyloid A^{114,453} inhibit HCV entry.

The tetraspanin CD81 binds tightly to the glycoprotein E2 via residues in the CD81 large extracellular loop.^{528,670,679} Antibodies targeting CD81 do not affect HCVpp binding to hepatocytes¹⁶⁶ but inhibit HCV infection after virus attachment.⁴²¹ Because HVR1 masks the CD81 binding site, a conformational change may be required to prime E2 for binding to this co-receptor.³⁷ CD81 interacts with another HCV entry factor, CLDN1,^{313,929} forming a complex that is essential for HCV infection.³¹² Receptor tyrosine kinases, such as epidermal growth factor receptor (EGFR), appear to regulate CD81–CLDN1 interactions and to promote HCV membrane fusion.⁵²⁷ Interaction of CD81 with another host factor, EWI-2wint, inhibits virus uptake.⁷³⁴ In addition to its role in entry, interaction of HCV with lymphocyte-expressed CD81 may contribute to the immune dysregulation seen in some patients with chronic infection.^{173,739,865}

Two tight junction proteins, CLDN1²²⁴ and OCLN,^{59,496,681} are essential for postbinding steps of HCV uptake. In addition, CLDN family members-6 and -9 can also mediate entry.⁵⁶³ The involvement of tight junction proteins suggests that HCV could traffic across the surface of the hepatocyte in order to engage all of its entry factors. Indeed, binding to CD81 activates a Rho guanosine triphosphatase (GTPase), which may mediate cytoskeleton rearrangements. Furthermore, recombinant E2 promotes relocation of CD81 to tight junctions.⁹⁴ In conflict with this hypothesis, however, is the finding that CLDN1

can form complexes with CD81 on the basolateral surface of hepatocytes.³¹² In addition, single particle tracking has visualized HCV internalization outside tight junctions—although this may represent the nonpolarized nature of the cultured hepatoma cells.¹⁵⁹

Following attachment, HCV is taken up via clathrin-mediated endocytosis.^{76,564} Internalized virions co-localize with clathrin light chain and the E3 ubiquitin ligase c-Cbl prior to uncoating.¹⁵⁹ Intracellular HCV is delivered to Rab5a-positive early endosomes,¹⁵⁹ which likely provide the acidic environment necessary to induce rearrangement of the HCV glycoproteins into their fusogenic form.^{343,864} Surprisingly, extracellular HCVcc particles are resistant to inactivation by low pH, suggesting that interactions at or near the cell surface prime the virus for fusion.⁸⁶⁴ This is functionally similar to pestiviruses⁴²⁵ but in contrast to flavivirus particles, which are primed during maturation,⁹⁴⁶ and to HCVpp,^{343,644} which have structural and compositional differences from authentic HCV particles.

Genome Structure

The HCV genome is an uncapped, 9.6-kb RNA containing highly structured 5' and 3' ends (Fig. 25.12A). The 5' NCR is a well-conserved, 341-nt sequence element that folds into a complex structure consisting of four major domains and a pseudoknot.³²⁴ The first 120 nt serves as a minimal replication element, although compelling genetic evidence shows that

the entire 5' NCR (or its complement in the negative strand) plays an important role in efficient positive-strand RNA synthesis.^{70,247,282,290,404,525,721} The 5' NCR also contains an IRES, which directs the cap-independent translation of the single large ORF.

Interestingly, the liver-specific micro-RNA (miR)-122 binds to two sites within the HCV 5' NCR, and these interactions are required for efficient viral replication.^{377,469} While miR-122 can stimulate IRES-mediated translation in an Argonaute 2-dependent manner,^{325,366,732,907} elegant genetic experiments revealed that a major function of miR-122 is to sequester the 5' end of the genome, perhaps protecting it from RNA degradation or from activation of innate antiviral responses.⁵³² Nuclease-resistant oligonucleotides that antagonize miR-122 function *in vivo* profoundly decrease HCV replication in experimentally infected chimpanzees and show promise for future therapeutics,⁴⁴⁷ although viral escape can occur in cell culture.⁴⁷⁴

A number of functionally important RNA structures have been identified within the HCV ORF.⁸⁶⁷ Genetic analysis indicated that an RNA stem-loop within the C gene is important for viral fitness.^{561,876} An RNA structure in NS5B, termed 5BSL3.2, forms a long-distance base-pairing interaction with upstream RNA sequences with the 3' NCR.²⁴⁶ This “kissing” interaction is essential for replication, although its function remains to be determined. In addition, the HCV ORF contains fewer UA and UU dinucleotides than expected

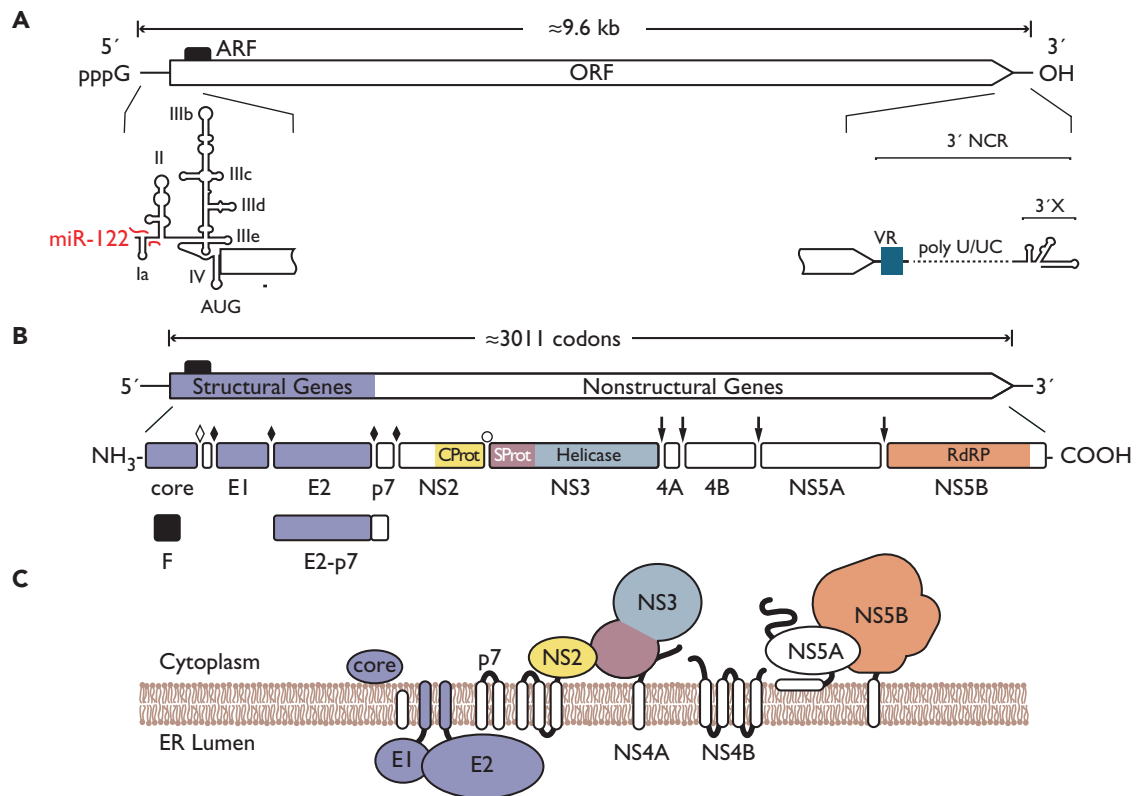

FIGURE 25.12. Hepacivirus genome structure and protein expression. **A:** Hepatitis C virus (HCV) genome structure and RNA elements. Important RNA elements are indicated as in Figure 25.4. The binding sites of micro-RNA (miR)-122 are indicated in red; the alternative reading frame (ARF) is indicated by a black box. **B:** Polyprotein processing and cleavage products. Cleavage sites are indicated as in Figure 25.4 except the NS2/3 cleavage, which is mediated by the NS2 cysteine autoprotease (open bullet). **C:** Polyprotein membrane topology. See the legend of Figure 25.4 for symbol definitions and the text for further details.

by chance.³⁰⁸ This is significant because these dinucleotides are the preferred cleavage sites of the IFN-stimulated RNase L. Based on the large-scale computerized folding of numerous positive-strand RNA viral genomes, the HCV ORF is also predicted to contain an unusually high rate of internal base pairing.⁷⁸⁹ Intriguingly, this feature is common among viruses that cause persistent infections. Thus, the observed bias in nucleotide composition and propensity for internal base pairing within the HCV ORF may reflect adaptation to evolutionary pressure exerted by innate antiviral pathways.

The 3' NCR was originally thought to terminate in polyadenosine or polyuridine. Improved methods for producing 3' terminal cDNAs later revealed, however, that the HCV 3' NCR actually consists of a short (~40 nt) variable domain and a polyuridine/polypyrimidine (polyU/UC) tract, followed by a highly conserved 98-nt 3' X domain.^{413,827} Mutagenesis studies revealed that the 3' X domain is essential for RNA replication and that the polyU/UC tract must be at least 26 nt in length.^{245,926,935,941} A number of cellular factors have been found to bind to the HCV 3' NCR, including RNA-binding proteins polypyrimidine-tract binding (PTB) protein,^{278,363,866} heterogeneous ribonuclear protein C,^{150,277} glyceraldehyde-3-phosphate dehydrogenase,⁶⁷¹ HuR,⁸⁰¹ and La autoantigen.⁷⁹⁹

Translation and Proteolytic Processing

In addition to its roles in replication, the HCV 5' NCR acts as an IRES to direct cap-independent translation of the viral genome. The IRES is encoded by 5' NCR domains II through IV (Fig. 25.12A), although flanking sequences can influence activity. In the current model of HCV IRES function, free 40S ribosomal subunits directly bind to the 5' NCR domains IIIId through f and adopt an mRNA-bound conformation.^{645,669,798} The IRES-40S complex then binds eIF3 and the ternary complex eIF2-GTP-Met-tRNA_i to form a 48S intermediate complex, in which the initiating AUG codon at nt 342 is positioned within the ribosomal P site.^{367,645} The HCV IRES directly interacts with eIF3 via determinants in domain IIIb¹⁶⁴ and thereby functionally mimics the 5' cap-binding complex eIF4E.⁷⁹³ Following GTP hydrolysis and release of eIF2, the 60S ribosomal subunit is recruited to form a translationally active 80S complex.^{367,645,669} Under some conditions the HCV IRES does not require eIF3 or ternary complex and is also capable of directing translation from non-AUG initiation sites.^{444,846} This mechanism, which utilizes eIF5B to recruit Met-tRNA_i, may allow the virus to initiate translation despite cellular eIF2 phosphorylation by the viral RNA sensor protein kinase R (PKR).

A number of cellular factors have been reported to contribute to HCV IRES activity. The human La protein stimulates translation by binding near the initiator AUG and recruiting the 40S ribosomal subunit^{168,693}; inhibiting La strongly decreases HCV gene expression and replication.^{168,194} Other host factors that stimulate HCV IRES activity include proteasome α -subunit PSMA7⁴²⁸ and nucleolin.³⁶⁵ In addition, polycytidine binding proteins 1 and 2 and PTB were shown to bind the 5' NCR, although their functions in the virus life cycle remain to be defined.⁴³ IRES-mediated translation can be inhibited by long-distance base pairing of 5' NCR nt 24 to 38 to a stem-loop region (nt 428 to 442) within the C gene region.⁴⁰⁵ Interestingly, this part of the 5' NCR overlaps with one of the miR-122 binding sites.³⁷⁷

Translation of the HCV genome produces a large polyprotein (~3,000 amino acids) that is proteolytically cleaved to produce 10 viral proteins (Fig. 25.12B): the virion structural components core (C) and glycoproteins E1 and E2, and the presumed NS proteins p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B. Mature forms of the HCV proteins arise via co- and posttranslational cleavage mediated by cellular and host-encoded proteases. During structural region processing, cleavages between C/E1, E1/E2, and E2/p7 are mediated by signal peptidase; mature C protein is released from the E1 signal peptide via signal peptide peptidase (SPP). Within the NS region, signal peptidase mediates cleavage of p7/NS2. The remainder of the NS region is processed by two virus-encoded proteases: the NS2 cysteine autoprotease mediates cleavage at the NS2/3 junction, whereas the NS3-4A serine protease cleaves at all downstream junctions (Fig. 25.12C).

In addition to proteins encoded by the large ORF, it appears that small protein products can be produced from the +1 reading frame of the C gene. At least three different forms of alternative reading frame protein (ARFP) have been described: ARFP/F (frameshift), ARFP/DF (double frameshift), or ARFP/S (short form). Although it is thought that these products are produced via ribosomal frameshifting, alternate translational initiation sites may also be involved.⁸⁹ It is equally unclear what role, if any, ARFP expression plays in the virus life cycle. Mutant genomes with a disrupted +1 reading frame are highly attenuated *in vivo*,^{561,876} although this may be due to disruption of conserved RNA secondary structures within the C gene.

Features of the Structural Proteins

C Protein

Core (C) is the first protein encoded by the HCV genome. It is among the most conserved of the viral proteins and is thought to multimerize and bind RNA to form the viral nucleocapsid. Proteolytic processing of the C protein occurs in two steps. First, the C/E1 junction is cleaved by host signal peptidase to yield a 191-amino acid, membrane-anchored form of C and the N-terminus of E1.³²⁹ Subsequent cleavage within the C-terminal membrane anchor by SPP liberates the mature form of C^{559,640,752,933} and is essential for infectivity.⁸³² The authentic SPP cleavage site has not yet been determined but likely occurs somewhere between residues 173 and 182³⁵¹; recent genetic evidence suggests that the C-terminus is at position 177.⁴¹⁹ In addition, N-terminally truncated forms of C have been described, but their mechanism of production is unknown.²¹⁸

Following removal of the membrane anchor, the mature C protein consists of two domains.⁸⁶ The N-terminal domain I (DI, ~120 amino acids) is hydrophilic and can bind RNA nonspecifically,⁷⁵² associate with the 5' NCR,^{783,828} and mediate dimerization of the RNA 3'X region.¹⁷¹ *In vitro*, interaction of DI with structured RNA can induce the assembly of nucleocapsid-like particles.⁴³¹ C protein likely dimerizes through homotypic binding elements in domains I and II,^{86,406,518,548} as well as a potential disulfide bond at Cys 128.⁴³² C protein has also been shown to associate with E1 and E2.^{49,502,623} Domain I may also be the target of phosphorylation by protein kinases A and C.⁵¹⁷

Domain II (~50 amino acids) contains primarily hydrophobic residues. *In vitro*, this domain is important for folding of truncated recombinant protein (residues 1 to 169) into an

α -helix-rich dimer.⁸⁶ DII is also important for localizing C to ER-associated lipid droplets,^{38,85,604} which play an important but unclear role in virus particle assembly.^{588,777} Lipid droplet association requires prior cleavage with SPP⁵⁵⁹ and is enhanced by the actions of diacylglycerol acyltransferase-1 (DGAT-1), an ER-resident enzyme that catalyzes a final step in triglyceride synthesis.³²⁶ It has been proposed that trafficking of C to lipid droplets increases the risk of liver steatosis in patients with chronic HCV, as well as promotes the development of steatosis in certain transgenic mice that overexpress the protein. Indeed, C binding to lipid droplets displaces adipocyte differentiation-related protein (ADRP) and leads to redistribution, clustering, and increased synthesis of these organelles in cell culture.^{84,190}

The HCV C protein has been implicated in numerous cellular pathways, including altered signaling, transcriptional control, apoptosis, and cellular transformation.^{558,845}

Envelope Glycoproteins

The HCV glycoproteins E1 (~30 kD) and E2 (~70 kD) form a noncovalent heterodimer that mediates viral attachment and membrane fusion. Both E1 and E2 are type I TM glycoproteins that contain a large extracellular domain and a single C-terminal TM domain. To generate this topology, the E1 and E2 TM segments, which each contain two short (<20 amino acids) hydrophobic stretches separated by charged residues, adopt an intramembrane hairpin structure during translocation. Following signal peptidase cleavage, the luminal C-termini reorient to face the cytoplasm, yielding tandem proteins each with a single membrane anchor.¹⁵⁶ Following biogenesis, the glycoproteins are retained in the ER.^{203,207,740}

Structural information regarding E1 is not available. Recently, however, biophysical characterization of the E2 ectodomain has produced a structural model that can be compared to flavivirus protein E.^{422,905} E2 is a three-domain protein with a high proportion of β -sheet, as well as random coil, β -turns and other natively unfolded regions; the overall structure of E2 is the same at both acidic and neutral pH.^{422,905} Three variable regions, including HVR1, can be deleted without affecting CD81 binding.⁵⁵⁴ HVR1 is followed by domain I (DI), which likely contains eight β -strands and includes the determinants of CD81 interaction. Several glycosylation sites cluster on DI and may shield the CD81 binding site from antibody neutralization. The highly conserved domain II (DII) is largely unstructured and includes the candidate fusion loop at residues 502 to 520; it also encompasses HVR2. The fusion peptide may be buried by contacts with E1 prior to fusion. Domain III (DIII) is connected to DII by an extendable linker encompassing the intergenotypic variable region (IgVR) and contains residues that may assist DI in CD81 binding. DIII is followed by a flexible stem that connects it to the TM domain.⁴²²

E1 and E2 likely associate as a class II fusion protein complex.⁹²² Formation of E1-E2 heterodimers is a slow process, with folding of each glycoprotein dependent on the other.^{95,582,653} and on the chaperone calnexin.²⁰⁴ Residues within the E1 and E2 TM domains are important for heterodimerization,⁶⁴² as are interactions of the ectodomains.⁹³⁶ The membrane proximal linker in E2 is also important for heterodimerization and HCVpp entry.²⁰² Construction of HCVpp bearing E1 and E2 from different genotypes indicates regions of intergenotypic

incompatibility in DI and HVRII and additional sequences in DII, IgVR, and the stem region of E2, confirming functionally important determinants.⁷ Although E1 and E2 interactions in the ER membrane are noncovalent, recent studies of infectious virions suggest that the assembled glycoproteins form large covalent complexes stabilized by disulfide bonds.⁸⁷⁹ These bridges may block acid-induced conformational changes until a trigger initiates entry, explaining the pH resistance of HCV particles.⁸⁶⁴

The HCV glycoproteins are important humoral antigens that can lead to virus neutralization and therefore employ strategies to evade the immune response. HVR1 is a major target of neutralizing antibodies.^{391,895} HVR1-specific antibodies can protect chimpanzees from infection with homologous HCV strains,²³¹ and early induction of HVR1-specific antibodies correlates with viral clearance in humans.^{11,965} To avoid neutralization, HVR1 exhibits a high level of sequence variability even within a single patient, largely driven by immunogenic selection.^{230,553,599,896} In addition, protein glycosylation likely also contributes to immune evasion by the envelope proteins. The E1 and E2 ectodomains are heavily N-glycosylated (generally 4 and 11 sites, respectively). Certain glycosylation site mutants are highly sensitive to neutralizing antibodies, suggesting the glycans mask conserved epitopes from the immune response.³²³ Glycosylation is also important for the proper folding and secretion of E2,⁷⁹⁵ as well as for the assembly and infectivity of HCVpp²⁷⁴ and HCVcc.³²³

Features of the Nonstructural Proteins

p7 Protein

p7 is a small (~7 kD) hydrophobic protein that spans the membrane twice, with ER-luminal N- and C-termini and a short, basic, cytoplasmic loop (Fig. 25.13A). Incomplete or delayed processing by host signal peptidase between E2, p7, and NS2 can lead to the production of E2-p7 and E2-p7-NS2.^{482,590,676,773} In model membrane systems, p7 multimerizes to form hexameric, cation-conductive membrane channels that are inhibited by amantadine and hexamethylene amiloride.^{294,519,600,659,689} (Fig. 25.13B).

HCV p7 is essential for virus assembly and infectivity *in vitro* and *in vivo*.^{373,750,809} In virus-producing cells, p7 was found to equilibrate pH gradients, reducing the number of acidic vesicles and raising the pH of lysosomes.⁹¹⁵ Interestingly, a p7 mutant that lacks channel activity could be complemented by the influenza M2 protein or by treatment with bafilomycin A1, demonstrating that p7 acts as a viroporin to modulate intracellular pH during virus production.⁹¹⁵ However, a p7 deletion mutant was not complemented by these treatments, suggesting that the protein plays an additional role during virus assembly. In this regard, p7 appears to interact with NS2 at a very early stage of virus morphogenesis.^{83,370,530}

NS2 Protein

NS2 (~23 kD) is a membrane-spanning protein with cysteine protease activity.^{287,330,513,770} The membrane topology of NS2 has not been fully elucidated but likely incorporates three N-terminal TM segments^{369,370} (Fig. 25.13C). The C-terminal region of NS2 contains the protease active site residues, His-952, Glu-972, and Cys-993.^{287,330,513} The only known function of this enzyme is to cleave the NS2/3 junction. Optimal autoprotease activity requires co-expression of NS2

FIGURE 25.13. Monomeric subunits are colored green and blue; active-site residues, red; C-terminal residues, yellow; co-crystallized detergent molecules are shown as spheres. Rendered from PDB number 2HD0.⁵¹³ **E:** A model of the full-length NS2, based on the models presented in **C** and **D**.

with the N-terminal zinc-binding domain of NS3, although the mechanism of enhancement is not clear.^{287,330,770} Notably, NS2/3 cleavage is inhibited by NS4A, the co-factor that promotes NS3 folding into a compact serine protease structure.¹⁷⁹

The x-ray crystal structure of the NS2 C-terminal domain demonstrated a cysteine protease with the active-site geometry of a serine protease.⁵¹³ The C-terminus of NS2 is bound in the substrate-binding pocket, suggesting that further protease activity is blocked following NS2/3 cleavage (Fig. 25.13D). Interestingly, the protease domain homodimerizes, leading to the formation of two composite active sites at the dimer interface. This architecture reveals a mechanism that can control polypeptide processing and explains the ability of some NS2-3 mutants bearing distinct defects to reform an active autoprotease *in trans*.^{287,716}

NS2 has an important albeit unclear role in virus particle assembly. Genetic experiments suggested that the N-terminal region of NS2 interacts with the structural proteins and/or p7, whereas downstream regions of NS2 interact with other NS proteins.⁶⁷⁵ Indeed, further genetic and biochemical studies confirm NS2 interactions with E1, E2, p7, NS3, and NS4A, indicating that NS2 contributes to virus particle assembly by bringing together viral structural and NS proteins.^{83,370,400,530,672,688,803}

NS3 Protein

HCV NS3 (~70 kD) is a multifunctional protein, containing an N-terminal serine protease domain and a C-terminal RNA helicase/NTPase domain.⁶⁰⁵ Both enzyme activities are critical for viral replication and have been characterized biochemically and structurally.

The serine protease domain of NS3 requires interaction with NS4A, as well as coordination of a structural Zn²⁺ ion,

for complete folding and enzyme activity.^{42,226,483} The NS3-4A protease is responsible for cleavage at the NS3/4A, NS4A/4B, NS4B/5A, and NS5A/5B sites.⁶⁰⁶ The protease first cleaves the NS3/4A site *in cis*, whereas subsequent cleavages occur *in trans*, with the preferred order NS5A/B > NS4A/B > NS4B/5A. Cleavage sites are well conserved and conform to the sequence (Asp/Glu)XXXX(Cys/Thr)/(Ser/Ala). In addition, NS3 has been shown to mediate internal cleavages within NS3, NS4B, and NS5A, although the functional relevance of these events is not yet known.⁴³

NS3-4A is structurally similar to other chymotrypsin-like proteases, with active site residues His-57, Asp-81, and Ser-139, and a substrate-binding surface located in a cleft between two β -barrel subdomains.⁶⁰⁶ The first subdomain includes an intercalated β -strand from the central region of NS4A. In the absence of the NS4A co-factor, the N-terminal 28 residues of NS3 remain flexible⁵⁵⁷ and the protein is rapidly degraded.⁹¹⁴ NS3 interacts with cellular membranes through two N-terminal amphipathic helices and through its interaction with NS4A.^{90,914} Interestingly, the structure of a single-chain, full-length NS3 shows the C-terminus coordinated by the serine protease, as would be expected from the *cis*-cleavage reaction⁹³⁰ (Fig. 25.7C).

The mechanism of protease activity initiates through deprotonation of Ser-139 by His-57; Ser-139 in turn acts as a nucleophile to attack the carbonyl carbon of the scissile peptide bond, forming a transient covalent link between the catalytic serine and C-terminal substrate. Dissociation of the N-terminal product allows hydrolysis of the tetrahedral intermediate to occur, regenerating the active site and C-terminal product. NS3-4A has an unusually shallow and hydrophobic substrate-binding surface that accommodates six amino acids.

However, the recognition of *trans*-cleaved substrates (NS4A/B, NS4B/5A, and NS5A/B) involves a relatively stable interaction between Cys residues at the substrate P1 position and a conserved Phe residue within NS3.⁶⁸⁰ This interaction slows the release of N-terminal products, which can inhibit subsequent catalysis.^{501,808} The discovery of this product-based inhibition led to the development of peptidomimetic compounds that potently inhibit NS3-4A serine protease activity and HCV replication *in vivo*.^{442,606} Interestingly, the preference for threonine at the P1 position of the NS3/4A cleavage site appears to reflect the selection of a substrate that is easily released following autocleavage.^{887,930}

In addition to its essential role in HCV polyprotein processing, NS3-4A serine protease manipulates the host cellular environment by cleaving the human mitochondrial antiviral-signaling (MAVS), TIR-domain-containing adapter-inducing interferon- β (TRIF), and tyrosine-protein phosphatase non-receptor type 2 (PTPN2) proteins (reviewed in⁶⁰⁶). MAVS is a key molecule involved in transducing signals from retinoic acid-inducible gene I (RIG-I) and melanoma differentiation-associated 5 (MDA5) proteins, which are cytoplasmic sensors of viral RNA that activate interferon regulatory factor-3 (IRF-3). TRIF is involved in the Toll-like receptor 3 pathway, which senses dsRNA in the extracellular and endolysosomal compartments. Thus, cleavage of MAVS and TRIF serves to subvert innate antiviral defenses.^{470,473,581} PTPN2 is a protein tyrosine phosphatase that resets the epithelial growth factor (EGF) receptor and other growth factor signals. Cleavage of PTPN2 may therefore contribute to altered cell growth and the development of liver cancer.⁹⁷

Similar to other *Flaviviridae*, the C-terminal domain of HCV NS3 encodes a superfamily 2 RNA helicase/NTPase. These enzymes utilize the energy derived from NTP hydrolysis to translocate along and unwind double-stranded nucleic acids.⁶⁹⁷ NS3 has been shown to unwind RNA and DNA homo- and heteroduplexes by binding to an unpaired region of a template strand and translocating in a 3' to 5' direction.^{43,306,339}

Like other RNA helicases, HCV NS3 contains two RecA-like subdomains with ATPase active site residues at their interface. *Flaviviridae* helicases also contain an α -helix-rich, third subdomain of unclear function. Co-crystallization studies revealed that nucleic acids are bound with a cleft formed between the first two subdomains and subdomain 3.^{402,538} The mechanism of NS3-4A helicase activity has recently been revealed through elegant structural biology, traditional ensemble enzymology, and single-molecule biophysical studies.^{29,205,301,467,468,774,775} NS3 sequentially translocates in the 3' to 5' direction along the tracking strand's phosphodiester backbone, unwinding one base pair for each ATP hydrolyzed.³⁰¹ Other studies have suggested a spring-loaded mechanism can lead to larger apparent step sizes of up to 3 nt.²⁹ Dimerization of NS3 helicase domains appears to facilitate cooperative unwinding of long templates. Helicase activity and substrate recognition are also stimulated by the NS3 serine protease domain and NS4A, and the helicase in turn stimulates NS3-4A serine protease activity.^{62,63,300,342,429,648} The helicase function of full-length NS3 can also be up-regulated by NS5B, presumably through interactions with the serine protease domain.⁹⁵⁴ Likewise, the NS3 helicase activity facilitates NS5B-mediated RNA synthesis.⁶⁷⁴ Helicase activity can be down-regulated by the cellular enzyme protein arginine N-methyltransferase 1 (PRMT1), which methylates one or

more arginines within the NTP-coordinating motif VI.^{206,724} In addition, many cell culture-adaptive mutations map to the surface of the helicase and to the region linking the protease and helicase,⁴³ suggesting that these are critical sites of protein interaction and/or conformational changes.

Although the precise roles of the NS3 helicase are not fully understood, the NTPase and helicase activities are essential for HCV replication and viral infectivity,^{414,441} and the helicase domain has been implicated in virus particle assembly.⁶¹⁷

NS4A and NS4B Proteins

NS4A is the smallest (~8 kD) NS protein, yet it has multiple functions in the virus life cycle. The central region of the protein acts as a co-factor for the serine protease and facilitates recognition of RNA substrates by the full-length NS3 protease/helicase.⁶¹ The hydrophobic N-terminal TM region of NS4A anchors NS3-4A to cellular membranes. NS4A also physically interacts with NS4B, NS5A, and uncleaved NS4B-5A.^{30,484} The acidic C-terminal region of NS4A contributes to HCV helicase activity,⁶¹ NS5A phosphorylation,^{383,407} RNA replication,⁴⁸⁹ and virus particle assembly.⁶⁷³

NS4B (~27 kD) is an integral membrane protein containing four central TM domains separating cytoplasmic N- and C-terminal regions.²⁸⁴ The N-terminal region of NS4B encodes two amphipathic helices, the second of which can alter its topology to insert in the membrane, and thereby invert the orientation of the first helix.^{284,520} The C-terminus of NS4B also encodes two α -helices, the second of which is membrane associated²⁸³ and can be palmitoylated.⁹⁴³ In addition, the central region of NS4B encodes a partially conserved nucleotide-binding motif and exhibits NTPase and adenylate kinase activities.^{212,854} NS4B can also bind RNA, with an affinity for the 3' terminus of the minus strand, and a small-molecule inhibitor of this activity decreases HCV replication.²¹³

NS4B forms oligomers and plays a critical role in organizing the membrane-bound replication complex.^{285,657,943} Expression of NS4B is sufficient to induce membrane alterations resembling the *membranous web*, where HCV RNA replication occurs.^{210,281} Consistent with an important role in RNA replication, a number of cell culture-adaptive mutations have been mapped to NS4B (reviewed in⁴³). NS4B has also been genetically linked to virus particle assembly, although its function in this process is not yet clear.³⁷⁵

NS5A Protein

NS5A (~56 to 58 kD) is a proline-rich, homodimeric, RNA-binding phosphoprotein that plays multiple roles in the viral life cycle. NS5A is a multidomain protein that contains an N-terminal Zn²⁺-binding domain I (DI), a central conserved domain II (DII), and a C-terminal variable domain III (DIII); these domains are separated by two short linkers of low complexity sequence (LCS).⁸⁴² DI includes an N-terminal amphipathic helix that mediates membrane association.^{91,214,665} X-ray crystallography revealed that DI adopts a novel protein fold and contains a unique Zn²⁺-binding motif⁸⁴³ (Fig. 25.14A, B). Interestingly, the same DI structure has been crystallized in two distinct homodimeric conformations: in one case DI formed a homodimeric claw with a basic groove postulated to bind RNA⁸⁴³; in the other case DI dimers formed a barrel-shaped structure⁵¹⁴ (Fig. 25.14B, C). Both dimer forms contain well-conserved residues at their interface, suggesting that these

FIGURE 25.14. Structures of hepatitis C virus (HCV) NS5A protein. **A:** Surface electrostatic potential of the dimeric NS5A zinc-binding domain, as rendered from PDB 1ZH1.⁸⁴³ Negative charges in red and positive charges in blue. **B:** The NS5A zinc-binding domain (PDB 1ZH1), with individual monomeric subunits colored purple and green. Zn^{2+} ions are shown in red, and coordinating residues are shown in yellow. **C:** An alternative structure of the NS5A zinc-binding domain, as rendered from PDB 3FQM.⁵¹⁴ The purple subunit is structurally aligned the same as the purple subunit in **B**.

alternate conformations may be functionally important—perhaps representing a molecular switch or a mechanism of higher-order oligomerization. NS5A homodimers have been observed in cell culture, although the dimer form was not resolved.³⁵² DII and DIII appear to contain natively unfolded regions, although NMR spectroscopy supports α -helical content within DIII.^{477,877} In line with this flexibility, DIII is tolerant of large deletions and insertions.^{27,345,495,556,605,841} One unusual feature of NS5A is a central region (amino acids 227 to 277), which overlaps the first LCS and part of DII, termed the IFN sensitivity-determining region (ISDR). Sequence variation within the ISDR was originally thought to correlate with IFN responsiveness in chronically infected patients, although the predictive value of this variation was later discredited.^{219,660} Nevertheless, the ISDR likely has other important functions, described later.

NS5A is phosphorylated by multiple cellular serine kinases and can be found in basally phosphorylated (56 kD) and hyperphosphorylated (58 kD) forms. The relevant cellular kinases and phosphoacceptor sites in NS5A are not fully characterized. Basal phosphorylation involves two regions of NS5A: a central region that encompasses the ISDR and a large C-terminal region of DIII.⁸³⁰ Basal phosphorylation likely involves casein kinase II or a related member of the CMCG kinase family, although other kinases have been implicated.^{158,346,347,353,401,717} Hyperphosphorylation involves residues in the first LCS, Ser-224, Ser-228, and Ser-231,⁸³⁰ although it is not clear whether these are the sites of hypophosphorylation or whether they are required for downstream phosphorylation events. NS5A hyperphosphorylation appears to be mediated by casein kinase I α ,^{702,703} although Polo-like kinase 1 has also been implicated in this process.¹³³ Furthermore, NS5A hyperphosphorylation requires the co-expression of NS3-5A *in cis*^{407,626} and interaction between NS5A and NS4A.^{30,383}

NS5A plays multiple key roles in RNA replication. The first line of evidence came from the identification of cell culture-adaptive mutations that enhance the replication efficiency of genotype 1a and 1b replicons, many of which mapped to hyperphosphorylation determinants within NS5A.^{43,77} Several adaptive mutations (including those in other NS proteins)

are associated with decreased NS5A hyperphosphorylation, suggesting that hyperphosphorylation negatively regulates replication.^{43,77} However small molecules that block NS5A hyperphosphorylation can either inhibit or enhance HCV replication depending on the viral genetic background,⁶²⁷ indicating that replication in cell culture may require a balance between different NS5A phosphoforms. Furthermore, cell culture-adaptive mutations associated with low hyperphosphorylation strongly inhibit HCV replication in chimpanzees.¹¹⁰ While the consequences of NS5A hyperphosphorylation are not fully understood, adaptive mutations associated with decreased hyperphosphorylation correlate with increased interaction between NS5A and hVAP-A,²²³ a cellular vesicle trafficking protein and putative HCV replication factor.²⁶⁰ Furthermore, an important function of NS5A is to bind to and activate PI4KIII α , a cellular lipid kinase that is essential for HCV replication complex formation.^{719,823} Consistent with this, NS5A localizes to sites of viral RNA synthesis.²⁸¹ NS5A also interacts with NS5B and can inhibit its RdRP activity *in vitro*,⁷⁸⁴ and NS5A mutations that block these interactions are detrimental for replication in cell culture.⁷⁸¹ Furthermore, NS5A binds G/U-rich RNA and exhibits a high affinity for the polypyrimidine tract of the HCV 3' NCR.³⁴⁵ The minimal RNA-binding domain of NS5A consists of DI and the first LCS,³⁵² although DII and DIII may contribute to RNA binding as well.²⁴² Finally, the RNA-binding ability of NS5A can be regulated by cyclophilin A (CypA), a cellular proline *cis-trans* isomerase that is essential for HCV replication.^{128,157,233,234,243,622,646,696,877,891,927}

NS5A also plays an important role in virus particle assembly, primarily through determinants in DIII.^{28,840} Specifically, virus assembly requires phosphorylation of NS5A residue Ser-457 by casein kinase II α .⁸⁴⁰ Interestingly, mutation of this residue resulted in decreased hyperphosphorylation, suggesting a possible switch between genome replication and virion assembly. Furthermore, virus morphogenesis is dependent on recruitment of NS5A to lipid droplets through its interaction with the C protein.^{28,546,588} NS5A also interacts with ApoE, an essential host factor for HCV particle assembly, and recruits annexin A2, a cellular phospholipid-binding protein that enhances virus production.³⁴

In addition to replication and assembly factors, NS5A has been reported to interact with numerous cellular partners in pathways such as signal transduction, transcriptional control, cell death regulation, and cell cycle control.³¹⁸ While the molecular details for many of these observations have not yet been elucidated, NS5A has been found to interact with p53, a tumor suppressor protein; Grb-2, an adaptor protein involved in mitogen signaling; phosphatidylinositol 3 kinase (PI3K), a lipid kinase involved in cell survival through the AKT pathway; FBL-2, a geranylgeranylated F-box protein that is required for the replication of genotype 1b replicons; SRCAP, an ATPase that activates cellular transcription; karyopherin β 3, a protein involved in nuclear trafficking; Cdk1/2, cyclin-dependent kinases that regulate cell cycle control; and Fyn, Hck, Lck, and Lyn, Src-family kinases.^{43,318} In addition, although the molecular consequences of the ISDR have not been explained, NS5A does appear to manipulate innate antiviral defenses. NS5A can bind to and antagonize PKR, a cytoplasmic sensor of dsRNA, as well as induce IL-8 expression, which can antagonize type I IFN responses.^{254–256,684–686}

Because of its important roles in the virus life cycle, NS5A is a promising target for antiviral drug design. Based on the requirement for interaction with CypA, HCV replication is potentially inhibited by cyclosporin A and derivatives.^{622,891} One promising candidate is DEBIO-025, which inhibits HCV replication but lacks cyclosporin's immunosuppressive effects.^{157,646} A new class of NS5A inhibitors was recently identified in a replicon-based screen, leading to compounds that appear to target DI and inhibit HCV replication at picomolar concentrations.^{261,464} Interestingly, the most potent compounds are symmetric, suggesting that they may bind to NS5A dimers.

NS5B Protein

NS5B (~68 kD) is the major enzyme of HCV RNA replication, the RdRP. Similar to other polymerases, NS5B has a right-hand structure, with distinct finger, palm, and thumb domains^{5,99,100} (Fig. 25.8B). HCV NS5B was the first RdRP to be structurally solved in a closed, active conformation, demonstrating extensive contacts between the finger and thumb domains surrounding a preformed active site. Subsequent studies showed that the active structure opens into an inactive form via movement of the thumb domain.⁷⁴ Conserved RdRP motifs and catalytic residues are primarily located in the palm domain and serve to properly align the RNA template, NTP substrates, and two divalent cations that catalyze nucleotide transfer (reviewed in⁸⁷²). Structures of NS5B in complex with divalent cations and NTP revealed an active-site geometry remarkably similar to human immunodeficiency virus (HIV) reverse transcriptase (an RNA-dependent DNA polymerase [RdDP]) and the RdRP of the dsRNA bacteriophage ϕ 6.^{99,637} In addition, a low-affinity GTP-binding pocket was identified at the interface of the thumb and finger domains.⁹⁹ Mutation of this GTP binding site has shown that it is dispensable for RdRP activity *in vitro* but critical for RNA replication in cell culture.^{115,707} The finger domain also contains a polar groove, which holds the template RNA; correct positioning of the template 3' end is ensured by a β -hairpin that protrudes from the thumb into the active-site cavity.^{338,637,707} This structure may act as a flap that is displaced during RNA synthesis to allow the dsRNA product to exit the polymerase core. The

polymerase also contains a C-terminal regulatory loop that wraps around the thumb and inserts into the active site, decreasing RNA binding and RdRP activity.^{466,707} In addition to the core RdRP structure, NS5B contains a 21-amino acid C-terminal hydrophobic tail that posttranslationally inserts into the ER membrane.^{364,766} Mutations that interfere with membrane association destroy RNA replication.^{462,603} Although the tail anchor can be functionally replaced with a heterologous membrane anchor,⁴⁶⁰ other evidence suggests that it contains important determinants for intramembrane protein–protein interaction.⁹² Nevertheless, tail anchor deletion mutants retain RdRP activity and permit the efficient expression and purification of soluble, active, recombinant NS5B for biochemical and structural studies.⁹²³

In vitro, NS5B has been shown to elongate annealed primers or self-priming copy-back templates.⁵⁶ RNA synthesis utilizes the divalent cations Mg^{2+} or Mn^{2+} to catalyze nucleotide incorporation at a rate of 150 to 200 nt/minute.^{508,638,708} NTP analogs containing 2'C-methyl groups are potent chain-terminating RdRP inhibitors of HCV and other *Flaviviridae*.¹⁸⁴ As the purine 2' position is not involved in catalysis, these compounds may impose steric constraints within the catalytic core. Resistance to these inhibitors is easily acquired in HCV by mutation of Ser-282-Thr in the NTP binding pocket, although this mutation has adverse effects on RNA replication.⁵⁸³

During authentic genome replication, NS5B is thought to initiate RNA synthesis *de novo* (i.e., without a primer).^{524,708,710,963} Comparative enzymatic studies showed that the efficiency of *de novo* initiation correlates with the efficiency of replication in cell culture, and that residue 405 on the thumb domain is an important determinant of initiation.^{767,786} As for other RNA polymerases, NS5B initiates with a purine nucleotide, which can be mono-, di-, or triphosphorylated.^{706,707,780} *De novo* initiation is destroyed by NS5B mutations that affect GTP binding but do not disrupt NTP incorporation.⁷¹² The β -hairpin and C-terminal regulatory loop of NS5B, which limit dsRNA binding, also control *de novo* initiation versus primed synthesis.^{136,466,707} High GTP concentrations may serve to structurally rearrange these elements, thereby favoring *de novo* initiation.³¹⁵ RNA templates that are efficiently used for *de novo* initiation, at least *in vitro*, contain limited secondary structure and an unpaired 3' end.³⁸⁵ NS5B can also utilize circular RNA templates, suggesting that a free 3' end is not absolutely required and that RNA is loaded when NS5B is in the open conformation.⁷⁰⁹ Nevertheless, the aforementioned template requirements are notably different from the natural site of HCV minus-strand initiation, the 3' NCR, which terminates with a uridylyl base paired in a stable stem-loop. When the HCV 3' NCR is used as a template in *de novo* initiation reactions, only internally initiated minus strands are produced.^{385,403,639,820} Addition of a few unpaired 3' nt, however, leads to the production of template-length minus-strand products.⁶³⁹ Thus, authentic initiation of HCV minus-strand synthesis may depend on the local unwinding of 3' secondary structures, perhaps by the NS3-4A helicase.

NS5B RdRP activity depends on higher-order interactions. Important contacts between NS5B domains were revealed through structural studies with nonnucleoside RdRP inhibitors (NNIs), which can allosterically block polymerase activity.^{74,139,153,191,299,515,859,860,885} In addition to intramolecular

interactions, oligomerization of NS5B leads to cooperative stimulation of polymerase activity,^{699,886} and the NS3-4A helicase can enhance primed RNA synthesis.⁶⁷⁴ Although both NS4B and NS5A mutations inhibit RNA synthesis,^{674,784} mutations in NS5A that inhibit interaction with NS5B are detrimental for RNA replication.⁷⁸¹ Genetic studies indicate that NS5B binds NS5A primarily via residues on the back of the thumb and inner surface of the fingers.⁶⁹⁹

In addition to template-directed RNA synthesis, NS5B may have terminal nucleotide transferase (TnTase) activity, adding one or a few untemplated nt to the 3' end of an RNA substrate.^{56,705,780} It should be noted that several reports did not detect this TnTase activity or showed that a cellular TnTase copurified with NS5B.^{390,508,638,923} Nevertheless, the TnTase activity of a highly purified NS5B preparation was shown to depend on RdRP active-site residues.^{705,712} Moreover, NS5B TnTase activity can convert an RNA lacking a 3' initiation site into a useful template for *de novo* initiation,⁷⁰⁵ suggesting that TnTase activity may contribute to maintaining genome integrity.

RNA Replication

Because many copies of the structural proteins are needed to package each nascent genome, *Flaviviridae* genomes must be translated more frequently than they are replicated. Indeed, HCV subgenomic replicon-bearing cells produce a ~1,000-to-1 molar ratio of viral proteins to viral RNA.⁷⁰¹ One way to achieve this is by cross-talk between the determinants that control translation and genome replication. For instance, the cellular PTB protein binds to the HCV 5' NCR and C coding region where it may modulate IRES activity,^{25,362,858} and to the 3' NCR where it may repress replication.^{362,866} Similarly, La protein was shown to bind to both HCV NCRs. For the related pestiviruses, several NF/NFAR proteins bind the 5' and 3' NCRs and regulate genome circularization, and might also be involved in regulating HCV translation versus replication.^{359,360} HCV translation may also be autoregulated through product inhibition: low levels of C protein can enhance IRES-mediated translation, whereas high concentrations inhibit it.^{82,955} Finally, it is interesting to note that polycytidine-binding protein 2 (PCBP-2) binds to the HCV 5' NCR.^{251,800} PCBP-2 also interacts with the 5' NCR and RdRP of another positive-strand RNA virus, poliovirus, to control the switch between translation and replication.²⁵⁹

HCV RNA replication takes place in a dense perinuclear matrix of ~85-nm vesicles termed the membranous web^{210,281} (Fig. 25.15). Several studies have shown that the membranous web is likely to be derived from the rough ER,⁴³ although these structures can be insoluble in nonionic detergents, suggesting that they are sphingomyelin rich.^{6,779} Formation of the membranous web is mediated by both NS4B²¹⁰ and NS5A⁷¹⁹ and may utilize autophagic pathways²⁰⁰ and activate ER stress.⁸³¹ The process of HCV replication also induces the expression of genes involved in lipid metabolism.^{192,387,818} Furthermore, replication is stimulated by increased availability of saturated and monounsaturated fatty acids and inhibited by polyunsaturated fatty acids or inhibitors of fatty acid synthesis,³⁸⁷ suggesting that specific lipids and/or membrane fluidity are important for the function of the membranous web. In addition, altering cholesterol metabolism pharmacologically can lead to the disassembly of the replicase and inhibit RNA replication due to reduced geranylgeranylation.^{387,934}

The HCV replicase can be accessed biochemically by using permeabilized cells, cell lysates, or membrane preparations isolated from HCV replicon-bearing cells.^{6,10,311,439,589,701,928} These *in vitro* systems allow the elongation of endogenous RNA templates to be studied, but they do not accept exogenous RNA. Nevertheless, the sensitivity of RNA synthesis to heparin³¹¹ and the pulse-chase metabolic labeling of single-stranded RNA (ssRNA) into dsRNA⁴³⁹ suggest that at least a limited amount of *de novo* synthesis occurs *in vitro*. Furthermore, *in vitro* RdRP activity is protected from nuclease and protease degradation by a detergent-sensitive membrane,^{589,701} suggesting that RNA synthesis is enclosed within the membranous web. These data support the hypothesis that active replicase is bound by a limiting membrane and demonstrate that a vast excess of NS proteins are produced. This enclosed replicase presumably includes a channel for the exchange of NTPs with nascent RNA and pyrophosphate, similar to the spherule structures proposed for other positive-strand RNA viruses.

Similar to other *Flaviviridae*, HCV RNA replication initiates with the synthesis of genome-length, negative-strand RNAs, which exist as partially double-stranded replicative intermediates or fully double-stranded replicative forms.¹⁰ Negative-strand RNA then serves as a template for multiple rounds of positive-strand synthesis, leading to the asymmetric

FIGURE 25.15. Membranous webs, the site of hepatitis C virus (HCV) RNA replication. A: Membrane alterations in Huh-7 cells harboring an HCV subgenomic replicon. **B:** Higher magnification of the membranous web (arrows). M, mitochondria; N, nucleus. (Courtesy of R. Gosert and D. Moradpour. Adapted from Gosert R, Egger D, Lohmann V, et al. Identification of the hepatitis C virus RNA replication complex in Huh-7 cells harboring subgenomic replicons. *J Virol* 2003;77[9]:5487–5492. Used with permission of the American Society for Microbiology Press.)

accumulation of nearly 10 positive strands for every negative strand.^{6,445,509,589,701} At least for cell culture–adapted genotype 1b replicons that do not make infectious virus, each cell contains approximately 100 negative strands, 1,000 positive-strands, and 1,000,000 copies of each viral protein.⁷⁰¹ A number of factors, however, influence the rate of HCV RNA replication. In Huh-7 cells, genotype 1b replication is robust in exponentially growing cells and repressed in growth-arrested cells.^{628,677,769} Interestingly, this block may be caused by a reduced pool of pyrimidine nucleotides, because replication can be restored in confluent cells by supplementing media with uridine and cytosine.⁶²⁸ In addition, co-transfected replicons interfere with each other, suggesting that they compete for limiting cellular factors.^{222,507} Given that replication-defective genomes also compete but that translation-defective genomes do not, one of these limiting cellular factors may interact with an NS protein.⁵⁰⁷

Virus Assembly

Similar to the related *Flaviviridae*, HCV particles bud directly into the ER, transit the secretory pathway, and are released through exocytosis. A model of HCV particle assembly has recently emerged, tying this process to the unique lipid metabolism of hepatocytes. Infectious virus production begins when SPP-processed core protein migrates to ER-associated cytoplasmic lipid droplets.⁵⁵⁹ Core is thought to recruit the membrane-associated replication complex through its interaction with NS5A,^{546,588,28} while the p7–NS2 complex recruits viral structural and NS proteins to the sites of virus assembly.^{83,370,530,672,688,803}

HCV particle formation is associated with VLDL assembly, which also takes place in the secretory pathway of hepatocytes. Consistent with this, inhibitors of serum lipoprotein assembly strongly inhibit HCV particle production,^{263,344} and NS5A has been shown to interact with apolipoproteins.^{60,176,223} During budding, nascent HCV particles may become associated with ER-luminal lipid droplets displaying ApoE. Lipid droplets are the triglyceride source for maturing VLDL particles and, *in vivo*, a large proportion may fuse with nascent ApoB-positive lipoproteins (reviewed in⁴⁴). HCV egresses through the secretory pathway, where the ion channel activity of p7 may protect nascent virions from premature fusion induced by the low pH of the secretory compartment.⁹¹⁵ While intracellular HCV particles are infectious, their buoyant density becomes lower as they egress in a maturation process that parallels VLDL.²⁶⁵ Like VLDL, blocking secretion of HCV leads to degradation of the high-density particles in a post-ER compartment.²⁶³

In addition to the VLDL secretory pathway, a number of other host factors have been implicated in HCV assembly, including the NS5A-associated factor annexin A2,³⁴ autophagy proteins Atg7 and beclin-1,⁸²⁹ and heat shock protein HSC70.⁶⁵²

PESTIVIRUSES

Background and Classification

Pestiviruses are animal pathogens of major economic importance for the livestock industry. They include the type member, bovine viral diarrhea virus (BVDV), as well as classical swine fever virus (CSFV) and border disease virus (BDV) of sheep.⁸⁵¹ New pestiviruses are frequently being isolated from

animals, bovine serum, or cell cultures. The International Committee on the Taxonomy of Viruses currently recognizes four pestivirus species (BVDV-1, BVDV-2, CSFV, and BDV) and four tentative species (atypical pestivirus, Bungerenga virus, giraffe-1 pestivirus, and pronghorn antelope pestivirus).^{271,494} Within the family *Flaviviridae*, pestiviruses show greater similarity in genome structure and mechanism of initiating translation to the hepaciviruses than to the flaviviruses.

Pestivirus infections can be subclinical or produce a range of symptoms, including acute diarrhea, hemorrhagic syndrome, acute fatal disease, and wasting disease (reviewed in⁸⁵²). CSFV, typically transmitted oronasally, leads to acute or chronic hemorrhagic syndromes with significant mortality. In contrast, ruminant pestiviruses usually result in subclinical infection or cause mild symptoms in adult animals. A notable exception is BVDV-2, which has been associated with a severe, acute hemorrhagic condition in cattle.^{165,664,714} In addition, diaplacental transmission of pestiviruses can cause fetal death, malformation, or persistent infection of the fetus; for cattle this can lead to the development of mucosal disease. Two biotypes of pestiviruses, cytopathic (cp) and noncytopathic (ncp) viruses, are distinguished by their ability to cause cytopathic effects in cell culture.

Live attenuated strains, inactivated virus preparations, and subunit vaccines are available for immunization against pestivirus-induced diseases.⁵⁹⁴ Such vaccines should prevent diaplacental infection. Early attempts at vaccination with an attenuated cpBVDV strain resulted in genome recombination and the emergence of fatal mucosal disease in persistently infected cattle.⁵³ While improved vaccines have been developed by combining multiple attenuating mutations,⁵⁷⁴ genetic recombination remains a concern.

Structure and Physical Properties of the Virion

Pestiviruses have been difficult to purify because of modest growth in cell culture, inefficient release from infected cells, and association with serum components and cellular debris.⁴⁵² Virus particles visualized by electron microscopy^{594,894} are spherical and 40 to 60 nm in diameter³⁴¹ (Fig. 25.16). Structure and symmetry of the core have not been characterized. In addition to the genome RNA and lipid envelope, the particles are composed of four structural proteins: the core protein (C) and three envelope glycoproteins, E^{ms} (for ribonuclease, secreted), E1, and E2.^{749,853} E^{ms} and E2 have been detected on the surface of CSFV and BVDV particles by immunogold labeling,⁸⁹⁴ and disulfide bonds connect the envelope proteins on the virion surface.⁸⁵³ Pestivirus virions have a buoyant density of 1.134 g/mL and are inactivated by heat, organic solvents, and detergents.⁷⁴⁶ Similar to HCV, virion infectivity is stable over a relatively broad range of pH.⁴⁸⁰

Binding and Entry

Binding and entry of pestiviruses involves initial attachment, interaction with specific receptor(s), internalization, and membrane fusion. Pestiviruses can be detected in a variety of tissue types *in vivo*, including epithelial cells, endothelial cells, PBMCs, the gastrointestinal tract, and neurons. Highly permissive cell lines for the propagation of pestiviruses and infectious cDNA clones have allowed the study of viral entry in culture. Bovine CD46 has been identified as a cellular receptor for

FIGURE 25.16. Pestivirus particles. **A:** Classical swine fever virus (CSFV) virions negatively stained with uranyl acetate **B:** Ultrathin section of swine testicular epitheloid cells infected with CSFV and immunostained with E^{ms}-specific monoclonal antibody (mAb) 24/16 and colloidal gold. Bar = 100 nm. (Courtesy of F. Weiland. Adapted from Weiland F, Weiland E, Unger G et al. Localization of pestiviral envelope proteins E^{ms} and E2 at the cell surface and on isolated particles. *J Gen Virol* 1999; 80[5]:1157–1165. Used with permission of Society for General Microbiology).

BVDV-1 and BVDV-2, including primary clinical isolates.⁵⁵¹ Experiments using chimeric CD46 molecules identified a discrete subregion within complement control protein repeat 1 as essential for BVDV binding and uptake.⁴²³ The viral ligand for CD46 is probably E2, which is also the major determinant of cell culture tropism, at least for ruminant pestiviruses.^{476,718} The LDL receptor was also suggested to assist in BVDV entry,⁴ although later evidence found no role for this molecule in bovine cell infection.⁴²⁴ In addition, E^{ms} of cell culture-adapted viruses binds cell surface glycosaminoglycans, which may act as an initial attachment factor.^{356,357} Finally, ectopically expressed E2 ectodomain inhibits BVDV entry at a step downstream of viral interaction with CD46, suggesting the involvement of an as-yet-unidentified entry factor.⁸⁶²

After binding, BVDV enters target cells via clathrin-dependent endocytosis followed by acid-dependent fusion in the endosome.^{297,425,457} Similar to HCV, BVDV must be primed to respond to low pH. Breakage of disulfide bonds between the glycoproteins during endocytosis may contribute to destabilizing the virion.⁴²⁵

Interestingly, E1 and E2 are sufficient for entry of CSFV or BVDV glycoprotein-pseudotyped particles; E^{ms} is nonessential in this system.^{737,888} Charged residues in the TM domains of E1 and E2 play a critical role in protein heterodimer formation and pseudoparticle entry.⁷³⁷

Genome Structure

Pestivirus genomes are approximately 12.3 kb in length.^{162,601} Similar to HCV, pestivirus genomes lack a 5′ cap and 3′ poly(A) tract^{102,601} (Fig. 25.17A). A long ORF of approximately 4,000 codons is flanked by a 5′ NCR of 372 to 385 nt and a 3′ NCR of 185 to 273 nt.^{32,102,160} Two 5′ terminal stem-loop structures in the BVDV genome (domains Ia and Ib in Fig. 25.17A) are important for efficient RNA replication.^{250,945} A 5′ terminal GUAU sequence is essential for BVDV replication, as its complement may be a promoter for plus-strand synthesis.²⁵⁰ Provided that this tetranucleotide sequence is retained, substitutions and deletions of hairpin Ia and part of Ib do not abolish replication.⁵² Thus, the 5′ signals essential for pestivirus genome replication are significantly shorter than for the hepaciviruses. Following the ORF, the 3′ NCR consists of a variable region,

a single-stranded region, and a conserved 3′ terminal stem-loop.^{189,944} Mutational analyses indicate that the terminal stem-loop and the upstream single-stranded region harbor important primary and secondary structural elements that probably function *in cis* to direct minus-strand initiation. In contrast, deletions in the variable region are well tolerated.^{360,650,944}

Translation and Polyprotein Processing

Cap-independent translation initiation of the pestivirus genome is mediated by an IRES that bears structural and functional similarity to that of HCV (compare Figs. 25.12A and 25.17A).^{103,189,687,729} The minimal pestivirus IRES includes 5′ NCR domains II and III and can be influenced by structured sequences downstream from the initiator AUG.^{142,621,687,729} As for HCV, the pestivirus IRES binds ribosomal 40S subunits without the need for translation initiation factors eIF4A, eIF4B, and eIF4F.^{668,669,794} The pestivirus genome encodes a large polyprotein that is processed into individual viral proteins: N^{pro}-C-E^{ms}-E1-E2-p7-NS2-NS3-NS4A-NS4B-NS5A-NS5B (Fig. 25.17B).^{161,163,578,602,695}

Unlike other *Flaviviridae*, the first pestivirus protein is an NS protein, N^{pro}. This is an autoprotease responsible for cleavage at the N^{pro}/C site.^{806,912} Processing of the pestivirus structural region appears to be mediated by at least three additional proteases. Host signal peptidase is believed to cleave at the C/E^{ms}, E1/E2, E2/p7, and p7/NS2 sites, with incomplete cleavage at the E2/p7 site leading to accumulation of an uncleaved product.^{215,310,749} SPP mediates further processing of the pestivirus C protein in the TM region.³²¹ The E^{ms}-E1 polyprotein (gp62) is processed slowly at a novel type of signal peptidase cleavage site.^{71,749} The NS region is processed by the NS2 autoprotease,⁴³⁷ which performs an incomplete cleavage at the NS2/3 junction,³ and the NS3-4A serine protease, which cleaves the remainder of the polyprotein.^{834,913,920} As detailed later, certain cytopathic pestiviruses generate the authentic N-terminus of NS3 via several different mechanisms.

N^{pro} Autoprotease

N^{pro} is an NS autoprotease that cleaves at a conserved site between Cys-168 and Ser-169 of the polyprotein.^{806,912} The active-site residues involved in this activity include Glu-22,

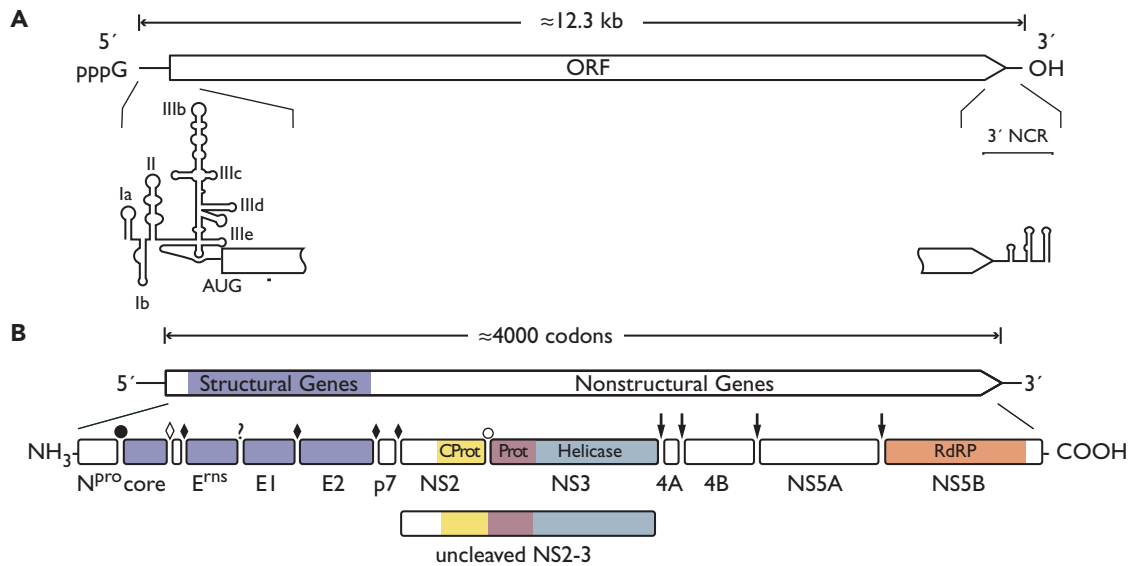

FIGURE 25.17. Pestivirus genome structure and protein expression. **A:** Genome structure and RNA elements. Important RNA elements are indicated as in Figure 25.4. **B:** Polyprotein processing and cleavage products. Symbols identifying proteolytic cleavages for the cpBVDV NADL strain are the same as those described in Figure 25.4 except for the proposed autocatalytic cleavage releasing the N-terminal nonstructural protein Npro from the pestivirus polyprotein, which is indicated by a closed bullet. See text for details.

His-49, and Cys-69, leading to the suggestion that N^{pro} may be an unusual subtilisin-like cysteine protease.⁷⁴⁷ N^{pro} is dispensable for pestivirus replication in cell culture but is required for virulence in animals.^{55,552,607,835,861} N^{pro} inhibits IFN production^{135,272,435,741,744} by targeting the cellular transcription factor IRF-3 for degradation.^{48,135,332,771} However, CSFV mutants that lack this activity remain virulent in animals.⁷⁴³

Pestivirus Structural Proteins

The capsid (C) protein is a 14-kD, highly basic, RNA-binding protein.⁶¹⁸ The N-terminus of C is generated by the autocleavage of N^{pro}.⁹¹² The nascent C protein encodes a C-terminal signal peptide that leads to translocation of E^{trns} into the ER. Similar to HCV, pestivirus C protein undergoes sequential maturational cleavages by signal peptidase and SPI.³²¹ Mature C is a natively unfolded protein that nonspecifically binds RNA with low affinity.⁶¹⁸ Remarkably, functional C protein can tolerate sizeable deletions, duplications, and insertions; for one of these mutants, severe defects in virus assembly were suppressed by a second site mutation in the NS3 helicase domain.⁷²⁷ These data suggest that C protein does not form an icosahedral nucleocapsid but may function like a histone protein to condense nucleic acids.

The E^{trns} glycoprotein (44 to 48 kD, formerly known as E0 or gp44/48) is heavily glycosylated on seven to nine asparagine residues and forms disulfide-linked homodimers.^{449,853} E^{trns} associates with membranes and virus particles via a C-terminal amphipathic helix^{235,847} but is also secreted from infected cells in soluble form.^{749,892,894} The most unusual feature of E^{trns} is that it encodes a ribonuclease (RNase) activity with specificity for uridine residues.^{316,768} This RNase activity contributes to the ability of pestiviruses to inhibit the induction of type I IFN by exogenous dsRNA.^{358,526,540,550,574} Antibodies that inhibit RNase activity tend to neutralize virus infectivity,⁹⁰⁸ and mutations in E^{trns} that destroy enzymatic activity give rise to viruses that are

attenuated *in vivo*.^{573,574,881} While homodimerization is dispensable for RNase activity,⁹⁰⁸ viral mutants that are unable to form E^{trns} complexes are less virulent,⁸⁴⁸ suggesting that the glycoprotein may have additional functions *in vivo*. Recombinant E^{trns} is toxic to lymphocytes *in vitro*,¹⁰⁴ which may contribute to the leukopenia seen in natural infections.⁸²¹ Although cytotoxicity is a feature of other soluble RNases,⁷⁶¹ it is not yet clear whether the enzymatic activity of E^{trns} is related to its toxicity. The C-terminal domain of E^{trns} can promote its translocation across cellular membranes, suggesting that it may have an intracellular target or function.⁴⁴⁸ Recombinant E^{trns}, however, can also bind strongly to the surface of cells, probably via interaction with glycosaminoglycans, and inhibit viral infection.^{356,894}

E1 and E2 are integral membrane glycoproteins that contain two to three and four to six N-linked glycosylation motifs, respectively.⁸⁹³ E2 forms homodimers,^{853,893} as well as disulfide-linked heterodimers with E1.⁷⁴⁹ Heterodimer formation is essential for viral entry and involves the interaction of charged residues within the TM domains of E1 and E2. Recombinant CSFV E2 can bind to cells and block infection of CSFV and BVDV, suggesting a common receptor or co-receptor for binding and entry of these pestiviruses.³⁴⁸ In addition, E2 expression inhibits BVDV superinfection at the level of viral entry.^{862,863} Infectious pestivirus particles are neutralized by monoclonal antibodies that recognize E^{trns} or E2,^{197,656,873,892,893,903} and these antigens can elicit protective immunity.^{349,748,874}

p7 Protein

The p7 protein consists of a central charged region separating hydrophobic termini. Similar to the HCV protein, pestivirus p7 is dispensable for RNA replication⁵⁵ but required for the production of infectious virus particles.^{310,475} Another similarity is that E2–p7 cleavage, most likely by host signal peptidase, is inefficient.²¹⁵ Uncleaved E2–p7 is not required for replication

in cell culture and both E2-p7 and p7 appear to remain cell associated.³¹⁰ Furthermore, pestivirus p7 protein may form ion channels *in vitro* and *in vivo*.^{295,528}

Pestivirus Nonstructural Proteins

The NS2 protein (~54 kD) is a cysteine autoprotease, distantly related to the NS2-3 autoprotease of HCV and GB viruses, which is responsible for processing NS2-3 (~125 kD).^{436,438} Remarkably, a cellular chaperone protein, DNAJC14 (originally identified as Jiv for J-domain protein interacting with viral protein), is an essential co-factor for NS2-mediated proteolysis. DNAJC14, a member of the heat shock protein (HSP) 40 family of chaperones, interacts irreversibly with NS2 and facilitates interaction of the catalytic and substrate residues.⁴³⁶ As discussed later, NS2-3 cleavage is essential for pestivirus RNA replication, and the efficiency of processing is a key regulator of RNA accumulation and cytopathogenicity. Interestingly, pestivirus NS2-3 cleavage is incomplete, and the unprocessed form of the protein is essential for infectious virus production.^{3,608}

As for other *Flaviviridae*, the pestivirus NS3 protein (~80 kD) contains an N-terminal serine protease domain^{50,279,913} and a C-terminal RNA helicase.²⁸⁰ The NS3 serine protease, along with its NS4A co-factor,^{836,920} cleaves between leucine and small uncharged amino acids: L↓(S/A/N).^{834,920} Substitutions that eliminate serine protease activity abolish viral RNA replication, confirming its essential role in virus viability.^{288,920} Interestingly, protease activity is retained when threonine is substituted for the serine nucleophile.⁸³⁶ The NS3 protein of BVDV has been purified and shown to possess RNA helicase⁸⁸⁹ and RNA-stimulated NTPase⁸²⁵ activities. Site-directed mutagenesis of the conserved helicase and NTPase motifs abolished viral replication.

The pestivirus NS4A (~10 kD) and NS4B (~38 kD) proteins share similar size, organization, and function with their HCV analogs, although sequence homology between the genera is negligible. NS4A is an essential co-factor for the NS3 serine protease activity.^{836,920} NS4B is a multispanning membrane protein that associates with rearranged cellular membranes involved in RNA replication.⁸⁹⁷ Similar to HCV, the pestivirus NS4B protein encodes an NTPase activity of unclear function.²⁷³ While a ~45 kD NS4A-4B precursor is transiently produced in pestivirus-infected cells, genetic analysis revealed that it is not essential for BVDV replication in cell culture.²⁵⁷

The remaining two proteins, NS5A (~58 kD) and NS5B (~75 kD), are present as mature cleavage products, as well as an uncleaved NS5A-5B precursor.^{161,163,443} NS5A is essential for RNA replication, although its precise functions have not been fully elucidated.^{289,844} Similar to HCV, pestivirus NS5A proteins contain an N-terminal amphipathic helix and a zinc-coordinating motif.^{93,753,844} Furthermore, NS5A is phosphorylated by a cellular serine or threonine kinase with properties similar to enzyme(s) that modify flavivirus NS5 and hepatitis virus NS5A.⁷¹⁵ Genetic analysis revealed that defects in the *NS5A* gene can be efficiently complemented *in trans*, whereas mutations in other pestivirus NS genes cannot.²⁸⁹

NS5B contains motifs characteristic of RdRP.¹⁶⁰ The RNA polymerase activity of recombinant NS5B has been characterized *in vitro* and found to extend template-primed RNA into double-stranded copy-back products^{440,510,807,960} or to catalyze *de novo* initiation from short, synthetic RNA or DNA templates.^{384,440} The structure of BVDV NS5B is similar to the

HCV polymerase and to other RdRPs, containing a palm subdomain surrounded by finger and thumb subdomains.¹⁴¹ The pestivirus NS5B structure reveals a unique N-terminal region, which suggests a role for GTP in *de novo* initiation, and provides a framework for understanding the molecular mechanisms of small-molecule inhibitors of BVDV replication.^{35,177,647,819}

RNA Replication

The basic mechanisms of pestivirus RNA replication appear to be similar to those described for HCV. RNA accumulation is associated with cytoplasmic membranes and requires NS3 through NS5B. Cellular components are also involved; for example, NFAR proteins associate specifically with the 5' and 3' termini of the BVDV genome.³⁵⁹ The 3' NCR also contains determinants that ensure efficient termination of translation, which is essential for efficient pestivirus RNA replication.³⁶⁰ Negative- and positive-strand RNAs have been detected from 4 to 6 hours after pestivirus infection, followed by the asymmetric synthesis of additional minus- and excess plus-strand RNA.²⁷⁵ Double-stranded RF RNA and partial duplex RI RNA have been tentatively identified.^{275,276,695}

Insights into the regulation of BVDV RNA replication and virus assembly have emerged from the study of ncp and cpBVDV. In addition to displaying differences in cytopathogenicity, both biotypes show altered NS2-3 processing. cpBVDV produces both NS3 and uncleaved NS2-3 in large amounts, whereas ncpBVDV was thought to express only the uncleaved protein. This suggested that uncleaved NS2-3 could serve as a functional RNA replicase component. It has been shown, however, that NS2/3 cleavage is absolutely required for RNA replication and that the efficiency of this process is regulated by the NS2 co-factor, DNAJC14.⁴³⁶ Early after ncpBVDV infection, NS2/3 cleavage is nearly complete, allowing efficient NS3 production and the initiation of RNA replication. At later time points, when uncomplexed DNAJC14 levels are limiting, autoprocessing becomes inefficient and viral RNA synthesis rates decline.⁴³⁷ cpBVDV viruses overcome the decline of endogenous DNAJC14 and promote continuous NS2-3 cleavage through a variety of genetic variations, as described later.

During replication, nonhomologous recombination can occur within pestivirus genomes and between pestivirus RNA and host cellular mRNA (reviewed in⁵⁸⁰). One likely mechanism is copy-choice template recruitment during minus-strand synthesis, which is consistent with the coding orientation of cellular inserts. An alternative mechanism of RNA recombination has been demonstrated by using a cell culture-based system in which homologous and nonhomologous recombination occurred between two overlapping transcripts that each lacked different essential parts of the viral RdRP.²⁵⁸ Statistical analysis of recombination sites also supports the hypothesis that homologous recombination contributes to pestivirus diversity in nature.³⁷⁶

Assembly and Release of Virus Particles

Other than the features of the virion structural proteins described previously, little information is available on the assembly and release of pestiviruses. Electron microscopic examination of infected cells suggests that pestiviruses mature in intracellular vesicles and are released by exocytosis.^{69,291} Consistent with intracellular budding, pestivirus envelope proteins are retained within the secretory pathway^{292,894} and

brefeldin A, a potent inhibitor of ER–Golgi transport, inhibits the secretion of viral particles but does not block their assembly.⁵³⁹ Interestingly, E^{rns} and E2 have been immunolocalized on isolated virus particles by electron microscopy, but E2 was not detected in particles undergoing secretion (or perhaps reattachment) at the cell surface.⁸⁹⁴ This suggests that E2 may be conformationally inaccessible to antibodies before maturation. As with other members of the *Flaviviridae*, NS proteins play an important role in pestivirus virion assembly or release, including p7, NS2-3, NS3-4A, and NS5B.^{3,24,475,608,617}

Pathogenesis of Mucosal Disease and the Generation of Cytopathic Pestiviruses

Mucosal disease, the most severe outcome of BVDV infection, is usually fatal.⁵⁸⁰ This disease occurs only after *in utero* infection with an ncpBVDV strain between 40 and 125 days of gestation, leading to the birth of immunotolerant animals that remain persistently infected for life. In the case of an animal exhibiting mucosal disease, both cp and ncp biotypes of BVDV can be found.⁵⁵⁵ The close serologic relatedness of isolated ncp–cp pairs led to the suggestion that cpBVDV might arise from ncpBVDV by a rare mutational event. Genetic characterization of a number of these ncp–cp pairs has verified this hypothesis and led to the remarkable discovery that most cpBVDV strains are generated via RNA recombination,⁵⁴ although a few cpBVDV strains lack obvious genome rearrangements.^{580,663} The presence of these genome rearrangements strongly cor-

relates with increased NS3 expression, enhanced RNA replication, and cytopathic effects in cell culture. Figure 25.18 illustrates a few of the remarkable cpBVDV genome alterations that have been discovered.

Common features of some cpBVDV variants include genome rearrangements or mutations that activate NS2-3 autoprotease activity, leading to increased production of NS3 and augmented RNA replication. For instance, strain NADL (Fig. 25.18A) contains a fragment of the cellular *DNAJC14* gene (also known as Jiv) inserted within NS2.⁷³¹ As described earlier, DNAJC14 is an essential co-factor of the NS2 protease, and overexpression of a critical 90-amino acid DNAJC14 subdomain enhances NS2-3 cleavage, regardless of whether the fragment is provided *in cis* or *in trans*.⁴³⁷ Interestingly, a much smaller insertion is found in the NS2 gene of cpBVDV strain CP7, which contains a 27-nt duplication from an upstream region of the NS2 gene in an alternate reading frame.⁸³⁷ As with the DNAJC14 fragment, this insertion leads to increased NS2-3 processing and a virus that is cytopathic in culture.^{567,576} Other viral insertions at or very close to the same site have been described.³⁶ For other cpBVDV isolates, increased NS2-3 autoprotease activity appears to result from point mutations that have accumulated within the NS2 gene.⁴³³

Another common rearrangement in cpBVDV isolates is the insertion of ubiquitin or ubiquitin-like genes immediately upstream of NS3,^{40,577,698,838} leading to NS2/3 processing by ubiquitin C-terminal hydrolase or related enzymes (e.g., strain

FIGURE 25.18. Genome rearrangements associated with cytopathic bovine viral diarrhea virus (cpBVDV). The **top diagram** indicates the polyprotein of a typical noncytopathic BVDV (ncpBVDV) isolate. Below, the polyproteins encoded by five different cpBVDV isolates generated by RNA recombination are shown. **A:** The genome of BVDV1 strain NADL. **B:** The genome of BVDV1 strain Osloss. **C:** The genome of BVDV1 strain CPI. **D:** The genome of BVDV1 strain Pe515CP. **E:** The genome of BVDV1 strain CP9. As discussed in the text, these cpBVDV polyprotein structures allow the production of both NS2-3 and NS3. In-frame insertions of host sequences (colored boxes) are present in NADL, Osloss, and CPI. The NS2 autoprotease is responsible for NS3 production in the NADL strain, but the inserted ubiquitin sequences in Osloss and CPI provide sites for processing by host ubiquitin C-terminal hydrolase (orange diamond). For Pe515CP and the CP9 DI RNA, the N^{pro} autoprotease (maroon box) mediates the cleavage producing the NS3 N terminus. The nomenclature and organization of the cleavage products and the symbols for the normal processing enzymes are defined in Figure 25.17.

Osloss) (Fig. 25.18B). In strains such as CP1, this may be accompanied by additional genome rearrangements, such as duplication of the *NS3* and *NS4A* genes⁵⁷⁸ (Fig. 25.18C). All the strains described previously also express uncleaved NS2-3, which is important for infectious virion production.³ Another type of insertion includes the light chain 3 gene of cellular microtubule-associated proteins, which is targeted for cleavage by a cellular protease.^{244,575}

A third type of cpBVDV genome configuration repositions the N^{pro} autoprotease immediately upstream of NS3. In strain Pe515CP, N^{pro} is duplicated together with the *NS3* and *NS4A* genes⁵⁷⁸ (Fig. 25.18D). Other cpBVDV isolates, such as CP9, contain a precise deletion of the C-E^{ms}-E1-E2-p7-NS2 coding region, resulting in an in-frame fusion of N^{pro} and NS3⁸³⁹ (Fig. 25.18E). Such subgenomic RNAs replicate autonomously but require ncpBVDV helper viruses to provide packaging functions *in trans*.⁵⁵ For CSFV, cp subgenomic RNAs have been isolated in which the entire coding sequence upstream of NS3 has been deleted.⁵⁷⁹

cpBVDV genome rearrangements strongly correlate with increased NS3 expression and enhanced RNA replication. These phenotypes, however, can be uncoupled from cytopathogenicity in cell culture. For instance, a temperature-sensitive mutant of CP7 containing a point mutation in NS2 is ncp at 39.5°C but retains high NS3 expression, although RNA replication is reduced.⁶⁴⁹ Selection for variants of cpBVDV in cell culture resulted in an ncpBVDV strain that still produces NS3 and viral RNA at levels comparable to the cp parent but encodes a point mutation in NS4B that attenuates the cytopathic effect.⁷⁰⁰ Other ncpBVDV strains also show changes in NS4B.²⁵⁷ Given that cpBVDV can cause ER stress³⁷⁸ and NS4B is involved in membrane reorganization,⁸⁹⁷ it seems plausible that cytopathic effects may result from overcommitment of cellular membranes to viral replication. Proteome analysis of infected cell cultures showed that cp or ncp viruses differentially regulate host signal transduction pathways, although these studies were not conducted with an isotype-matched cp–ncp pair of viruses.²¹ In infected animals, increased cell death may be sufficient to induce widespread tissue injury and inflammation. Animals with mucosal disease also show increased numbers of infected cells, suggesting that differences in cpBVDV tropism may also contribute to the disease.⁴⁷⁹

GB VIRUSES

Discovery and Classification

In the early 1990s, a residual number of hepatitis cases were still not attributable to hepatitis A through E viruses. Efforts aimed at identifying additional hepatitis agents revealed three novel viruses that have been tentatively assigned to the family *Flaviviridae*. Two of these viruses, GBV-A and GBV-B, were cloned via representational difference analysis from the sera of tamarins experimentally infected with the GB hepatitis agent.⁷⁹² The GB agent was originally derived from the serum of a 34-year-old surgeon, “GB,” who had acute hepatitis, by serial passage in tamarins.¹⁸⁸ Both viruses are similar to HCV yet genetically quite distinct.⁶⁰⁹ Although originally derived from a human hepatitis case, subsequent work showed that GBV-A is an indigenous monkey virus that was likely acquired during passage in tamarins.^{107,456} Some human cases that are not A through E

hepatitis show serologic reactivity to both GBV-A and GBV-B, but reverse transcription-polymerase chain reaction (RT-PCR) has failed to detect either virus in human samples. Rather, a third related virus, GBV-C, was subsequently identified in humans.⁷⁹¹ Working independently, another group that was immunoscreening cDNA libraries from non-A, non-B hepatitis cases identified an agent, initially termed hepatitis G virus (HGV), which later turned out to be an independent isolate of GBV-C.⁴⁹³ Because this virus has not been convincingly shown to cause human disease, including hepatitis, we will refer to it by its original designation, GBV-C.

A virus distantly related to GBV-A and GBV-C was recently discovered in Old World frugivorous bats in Bangladesh.²²⁰ This virus has been designated GBV-D.

Based on sequence relatedness and overall genome structure, GBVs have been classified as members of the family *Flaviviridae*. GBV-B is considered to be a member of the genus *Hepacivirus*.⁸⁵¹ It has recently been proposed that GBV-A, GBV-C, and GBV-D be classified as a separate genus, *Pegivirus*, although this awaits formal ratification by taxonomists.⁸⁰⁵ According to the proposed classification strategy, GBV-B would be renamed GBV and other GBVs would be renamed as pegiviruses according to their host of origin.

The inability to detect GBV-A or GBV-B in human samples led to investigation into their origins. Interestingly, GBV-A has been detected in several species of New World monkeys in the absence of experimental infection or overt disease.^{107,455} Viral sequences isolated from a single primate species are highly related, whereas sequences derived from separate species show greater divergence, indicating that GBV-A has adapted to its primate hosts over extended periods of time.^{107,127,455} The distribution of GBV-B in nature is unknown because the only source of this virus is the original tamarin-passaged GB serum. Despite intensive efforts, it has not been reisolated from natural sources.

Since its initial discovery, GBV-C infection has been found to be surprisingly common in the human population. Approximately 15% of healthy volunteer blood donors have markers of previous or ongoing infection with this virus,⁸⁰⁴ and GBV-C has also been found in chimpanzees.^{2,72,595} Phylogenetic analysis of GBV-C sequences has been complicated by an apparent bias against synonymous substitutions in some parts of the genome, leading to differences in inferred evolutionary relationships.⁷⁸⁷ The molecular basis for this bias is unclear but may involve evolutionary constraints imposed by RNA structures⁷⁸⁹ or cryptic ORFs.^{658,796} Nevertheless, GBV-C has been classified into four or five genotypes.⁷⁸⁷ Remarkably, variation among GBV-C isolates reflects the geographic distribution of human migration, suggesting the long-term co-evolution of this virus and its host. Given the rate at which RNA viruses typically evolve, this finding suggests that GBV-C is subject to unusual evolutionary constraints.

Clinical Perspective

Although GBV-A and GBV-B were originally derived from a case of human hepatitis, it is unclear whether either virus was the cause of the disease. It is now clear that GBV-A is not associated with any known disease and is likely to have been acquired during tamarin passage. GBV-B can infect and cause hepatitis in New World monkeys such as tamarins, marmosets, and owl monkeys, but it does not infect chimpanzees.^{101,108,446} Because

of this preference for lower primates, GBV-B is unlikely to be a human virus. Attempts to identify GBVs in the original GB clinical sample have failed, possibly because of degradation over prolonged storage.^{2,763}

Human infection with GBV-C is well documented, although direct association of this virus with any human disease has proved to be elusive.⁸⁰⁴ While the virus is usually cleared within 2 years,⁶⁴ persistent infections can last for years without clinical effects.¹⁷ Clearance usually correlates with the appearance of antibodies against the viral E2 glycoprotein.⁸⁰⁴ GBV-C appears to be primarily lymphotropic *in vivo*,^{450,451} although evidence also exists for hepatotropic isolates.²⁴⁰ GBV-C is transmitted parenterally or sexually, and a vertical transmission route is also likely.^{65,804} Because these routes also transmit many other human viruses, GBV-C co-infections with HBV, HCV, or HIV are not uncommon. Needless to say, co-infection with human hepatitis viruses has likely contributed to the confusing association of GBV-C with disease.

Intriguingly, there is a possible interaction between GBV-C and HIV. It has been noted that patients co-infected with the two viruses tend to have higher CD4⁺ T-cell counts, lower HIV titers, and slower HIV disease progression.⁸⁰⁴ Based on these observations, as well as *in vitro* experiments, it has been proposed that GBV-C may interfere with HIV replication by altering expression of cytokines, chemokines, and chemokine receptors,^{683,918} decreasing T-cell activation,⁵⁴¹ directly inhibiting HIV-1 entry,^{327,381,408,596} or eliciting cross-reactive antibodies that neutralize HIV particles.⁵⁹⁷ It has also been argued, however, that as a lymphotropic virus, the presence of GBV-C viremia may simply reflect the higher CD4⁺ counts in HIV nonprogressors.⁸⁷⁰ Thus, the underlying reasons for the correlation between GBV-C infection and slower HIV progression are not yet clear.

Experimental Systems

Little work has been done on GBV-A because it is an indigenous monkey virus that is not associated with disease. On the other hand, GBV-B is the closest relative of HCV and has been extensively studied as a surrogate model system. GBV-B can be readily cultured in primary tamarin or marmoset hepatocytes^{51,101,446} but replicates poorly (if at all) in many immortalized cell lines.¹⁰⁵ Full-length GBV-B cDNAs have been assembled and shown to be infectious and cause hepatitis in tamarins.^{109,545,757} Based on these functional clones, subgenomic GBV-B replicons have been constructed and can replicate in the human hepatoma lines Huh-7 and Hep3B, albeit with low efficiency.^{186,187}

GBV-C has been reportedly cultured in human hepatoma lines,⁷⁷² primary human lymphocytes,²⁶⁷ peripheral blood mononuclear cells,²⁴¹ and a derivative of the Daudi Burkitt lymphoma line.⁷⁸² Reminiscent of HCV, replication levels are low in these cell culture systems. Nevertheless, a GBV-C cDNA clone was constructed and shown to be infectious in primary human CD4⁺ T-cells.⁹¹⁹ GBV-C subgenomic replicons can persistently replicate in Huh-7 cells.¹¹⁸

Virion Structure and Entry

Particles of GBV-A and GBV-B have not been characterized. Similar to HCV, GBV-C particles exhibit unusually low and heterogeneous buoyant density, with peaks near 1.07 to 1.09 g/mL and 1.17 g/mL^{566,754,917} due to interaction with lipoproteins.

Treatment with detergents or organic solvents removes the viral envelope and shifts the peak of viral RNA to a higher-density form that may represent nucleocapsids,^{566,754,917} although, paradoxically, GBV-A and GBV-C do not encode an obvious capsid gene. Little is known about the entry mechanism of GBV, although it has been proposed that GBV-C utilizes the LDL receptor.⁴

Genome Structure and Expression

As with other *Flaviviridae*, the GBVs encode a single long ORF containing structural genes followed by NS genes, flanked by 5' and 3' NCRs.^{456,609} As for HCV and the pestiviruses, GBVs utilize an IRES to direct cap-independent translation.^{286,790} Compared to other *Flaviviridae*, however, the GBV-A and GBV-C 5' NCRs are much longer (>500 nt) and appear to fold into a similar structure that differs from other family members. The GBV-B 5' NCR is also much longer than the corresponding HCV sequence, but the two regions share significant similarities in primary, secondary, and tertiary structure. In fact, critical regions of the GBV-B and HCV IRESs can be functionally exchanged.^{380,728,730}

The GBV-A and GBV-C 3' NCRs lack a poly(U/UC) tract and are highly conserved only within these virus groups, with the exception of more broadly conserved terminal stem-loop structures.^{174,919} The GBV-B 3' NCR is 361 nt long, containing a short poly(U) stretch 30 nt downstream of the stop codon, followed by a unique 309-nt sequence.^{109,756} Although this region of the GBV-B genome does not display homology to HCV, the terminal 82 nt of the sequence can fold into a structure reminiscent of the HCV 3' X region.

As with HCV, GBV-B contains a basic capsid protein followed by two envelope glycoproteins, E1 and E2. The genomes for GBV-A and GBV-C also contain E1 and E2 glycoproteins, but they lack any obvious capsid-like sequence.^{493,609} The initiation codons used by these viruses have not been firmly mapped but appear to be conserved AUG codons immediately upstream of the E1 gene.⁷⁹⁰ It has been observed, however, that individuals infected with GBV-C generate antibodies against a small basic peptide that can be translated from an in-frame upstream AUG, suggesting that such a protein is expressed *in vivo*.⁹¹⁷ Alternative explanations for the lack of a capsid-like protein include the possibilities that GBV-A and GBV-C might usurp a capsid-like protein from the host cell or a co-infecting virus, or that additional GBV proteins may be involved. In this regard, a region of the GBV-C NS5A gene exhibiting a bias against synonymous mutation has been noted to potentially encode a small basic protein (10 kD, pI 11.5) in an alternate reading frame.⁶⁵⁸ Further characterization of GBV-A and GBV-C particles will be needed to demonstrate the nature of their nucleocapsid.

GBV-B encodes a 13-kD protein that shows partial homology to HCV p7.²⁷⁰ This protein is predicted to span the membrane four times and can be processed by signal peptidase into two tandem p7-like proteins.^{270,824} Remarkably, only the second half of p13, which has greater similarity to the HCV p7 gene, is needed for infectivity in tamarins.⁸²⁴ Furthermore, the GBV-B p13 gene can be functionally replaced by HCV p7.²⁹³

The NS proteins of GBVs show the greatest similarity to HCV, and the boundaries of cognate NS2, NS3, NS4A, NS4B, NS5A, and NS5B proteins have been proposed.^{456,609} Catalytic residues of the HCV NS2/3 autoprotease are conserved

among GBV NS2 proteins, and this enzymatic activity has been demonstrated for GBV-C.⁵⁷ Similarly, the GBV NS3 proteins encode an N-terminal serine protease and C-terminal RNA helicases.^{456,609} The GBV-B serine protease activity shares substrate specificity with the HCV enzyme and requires the virus-specific NS4A co-factor.^{111,755,759} Consistent with this high degree of similarity, inhibitors of the HCV serine protease also inhibit the GBV-B protease.¹⁰¹ NTP-dependent RNA helicase activity has also been demonstrated for NS3 proteins of GBV-B and GBV-C.^{307,961} The GBV-B NS5B has been shown to possess primer-dependent and *de novo* initiation RdRP and terminal transferase activities, albeit with different cation selectivity.^{711,962} The tail anchor of GBV-B NS5B can functionally substitute for the tail anchor of HCV NS5B.⁹²

PERSPECTIVES

Our understanding of the *Flaviviridae* has increased tremendously in the recent years, although significant gaps remain. The recent identification of new members of the *Flaviviridae* such as the GBVs and CHV has deep implications for understanding the origins and diversity of these viruses. For a few viruses in the family, viral and host proteins required for genome replication have been identified and some of them have been characterized in molecular detail. A major remaining task is to understand how these components come together to form a functional replicase. Similarly, the processes of virus entry and particle assembly are only incompletely understood. It is very curious that flaviviruses and pestiviruses can tolerate large deletions and insertions within their C genes, and that some GBVs lack recognizable nucleocapsid genes altogether. These observations suggest that alternative mechanisms must allow viral genomes to condense into small virus particles. It is also curious that HCV assembly has been tied to VLDL assembly, although the molecular basis for this association remains unclear. Finally, a major overarching goal is to translate our knowledge of these viruses into improvements in human and animal health. The recent development of HCV-specific antivirals demonstrates the feasibility of this approach, although major challenges remain to develop broadly acting antiviral strategies. Similarly, vaccine development remains an important priority, particularly for dengue and HCV, with no clear solutions in sight. Clearly, we have only just begun to understand the *Flaviviridae*.

Acknowledgments

Flaviviruses acquired their name from the jaundice associated with the liver dysfunction caused by yellow fever virus (YFV) infections. YFV played an important historical role in defining the nature of viruses in general. Seminal studies by Walter Reed and colleagues⁷⁸⁰ demonstrated that the etiology of yellow fever was a filterable agent that could be transmitted through the bite of a mosquito, confirming the postulates of Carlos Finlay. YFV was the first flavivirus isolated (in 1927) and the first to be propagated *in vitro*.^{790,820} These advances led remarkably rapidly to the development of an effective YFV vaccine that remains in use today.⁵⁶⁹ Experiments with the louping ill virus (LIV) in 1931 established that ticks also were capable of transmitting viruses associated with human disease.¹¹⁹ The discovery that antisera raised against some, but not all, viruses that caused similar diseases (e.g., encephalitis) cross-reacted with heterologous viruses provided a method to investigate the relatedness of flaviviruses.^{126–128,876} This was refined further with the development of a standardized hemagglutination inhibition test that allowed classification of 10 different flaviviruses and distinguished them from alphaviruses.¹²⁷ These two groups of viruses were referred to thereafter as group A and B arboviruses, respectively. The first full-length flavivirus genome (YFV) were sequenced in 1985 by Charles Rice and colleagues.⁶⁸⁰ Subsequent advances in the molecular genetics of flaviviruses have increased our understanding of the relationships between viruses that was originally revealed by serology (described below). Seventy-three viruses of the *Flavivirus* genus (classified as 53 distinct species) have since been defined (<http://www.ICTVonline.org/index.asp>).

FLAVIVIRUS DIVERSITY, EVOLUTION, AND DISTRIBUTION

Molecular Phylogeny

Phylogenetic relationships among members of the flavivirus genus have been established through the analysis of individual genes, and, more recently, the entire open reading frame of the genome.^{73,160,248,274,275,402,435,910} Analysis of the phylogenetic tree of flaviviruses with respect to key features of the biology and ecology of these viruses has proven insightful.^{248,271} Three groups of viruses are defined based on their mode of transmission: tick-borne flaviviruses (TBFVs), mosquito-borne flaviviruses (MBFVs), and those flaviviruses with no known vector (NKV). The earliest divergence from a monophyletic origin separates flaviviruses based on their mode of transmission.^{435,528} One lineage arising from the earliest branch of the phylogenetic tree contains viruses transmitted by ticks and two groups of NKV viruses (Fig. 26.1). The second includes the mosquito-borne viruses and the Entebbe bat virus (ENTV) group of NKV viruses.⁴⁰² The MBFVs are grouped further as a function of their association with mosquitoes of the *Aedes* and *Culex* genera. Viruses in these two clades cause hemorrhagic disease and encephalitis in humans and livestock, respectively. Although many of the viruses in the *Culex* clade infect avian hosts, *Aedes* viruses generally do not. Conversely, *Culex* viruses are not maintained in nature in infection cycles involving primates.

The tick-borne flaviviruses include 12 species divided into three groups^{274,402} (Fig. 26.1). The largest group of TBFVs is associated with mammalian hosts (typically rodents), and includes viruses that cause encephalitis (e.g., tick-borne encephalitis viruses [TBEVs]) and hemorrhagic fever (Omsk hemorrhagic fever virus [OHFV] and Kyasanur Forest disease virus [KFDV]) in humans. In addition, three species of mammalian TBFVs have not been associated with disease (Royal Farm virus [RFV], Karshi virus [KSIV], and Gadgets Gully virus [GGYV]). Viruses of the TBEV serocomplex are thought to represent a continuous evolutionary cline (a genetic gradient) that originated in Africa and moved from east to west across the Northern Hemisphere; the genetic distance between viruses in the mammalian tick-borne group correlates with increases in geographic distance.^{274,910} This is reflected by the asymmetric branching pattern of the phylogenetic tree of the

mammalian viruses⁹¹¹ (Fig. 26.1). The evolution of RFV, KSIV, and GGYV is not associated with this TBEV serocomplex cline, nor understood. This second group of TBFVs replicates within seabirds and ornithophilic ticks but does not cause disease in humans. These viruses have a broad geographic range that presumably reflects the migratory patterns of their avian hosts.^{271,274} The sole member of the final group of TBFVs is the Kadam virus (KADV). KADV is found in Africa and is typically associated with livestock.²⁷¹ An understanding of the relationship between KADV and other members of the TBFVs has evolved. Although these viruses have been assigned to both the mammalian or sea bird groups of flaviviruses, a more recent analysis of the complete coding sequence of TBFVs places this virus in its own group, which is supported by unique features of its envelope protein and the fact that it encodes a polyprotein that is smaller than the rest of the TBFVs.²⁷⁴

MBFVs diverged early into two lineages; viruses within each of these lineages are subdivided based on their association with mosquitoes of the *Aedes* genus or *Culex* genus^{275,402} (Fig. 26.1). Viruses of the *Aedes* clade are a paraphyletic group thought to predate and give rise to the *Culex* viruses.²⁷¹ One branch of the MBFV portion of the phylogenetic tree includes viruses of the YFV group, the recently proposed Edge Hill virus (EHV) group, and two NKV viruses, discussed below. The YFV group includes Wesselsbron virus (WESSV), Sepik virus (SEPV), and YFV. WESSV is a veterinary pathogen transmitted by *Aedes* mosquitoes that causes a nonfatal febrile illness in humans. Very little is known about the clinical significance and vector biology of SEPV infection. Both SEPV and WESSV are found in Africa and Asia.²⁷⁵ The seven viruses of the EHV group are transmitted predominantly by *Aedes* mosquitoes, are found primarily in Africa (except for EHV, which is present in Australia), and share the unique property of encoding five (instead of six) disulfide bridges in the envelope glycoprotein. Human cases have been associated only with Banzi virus infection (BANV).²⁷⁵ The second branch of the MBFV phylogenetic tree contains dengue viruses (DENVs), which are transmitted by *Aedes* mosquitoes, a large group of viruses vectored by *Culex* mosquitoes (e.g., Japanese encephalitis virus [JEV], West Nile virus [WNV]), and a group of *Aedes*-vectored viruses closely related to the *Culex* flaviviruses (e.g., Spondweni virus, SPOV).⁴⁰² The diversity of viruses in the JEV serocomplex and DENV is described in detail below.

FIGURE 26.1. Phylogenetic tree of viruses in the genus *Flavivirus* reveals the evolutionary relationships among viruses transmitted by different vectors. A maximum-likelihood tree was generated using the complete polyprotein sequence of the indicated flaviviruses as detailed by Kitchen and colleagues.⁴⁰² The viral taxa are abbreviated and colored according to their mode of transmission. The host reservoir for each virus is indicated in gray. Viruses that frequently cause disease in humans are indicated with red asterisks. APOIV, Apoi virus; MODV, Modoc virus; MMLV, Montana myotis leukoencephalitis virus; RBV, Rio Bravo virus; TYUV, Tyulenyi virus; MEAV, Meaban virus; SREV, Saumaurez Reef virus; KADV, Kadam virus; GGYV, Gadgets Gully virus; KSIV, Karshi virus; RFV, Royal Farm virus; DTV, Deer tick virus; POWV, Powassan virus; AHFV, Alkhurma hemorrhagic fever virus; KFDV, Kyasanur Forest disease virus; LGTV, Langat virus (LGTV); OHFV, Omsk hemorrhagic fever virus; TBEV-FE, Tick-borne encephalitis virus-far eastern subtype; TBEV-S, Tick-borne encephalitis virus-Siberian subtype; GGEV, Greek goat encephalomyelitis virus; TSEV, Turkish sheep encephalitis virus; TBEV-E, Tick-borne encephalitis virus-European subtype; LIV, Louping ill virus; SSEV, Spanish sheep encephalomyelitis virus; ENTV, Entebbe bat virus; YOKV, Yokose virus; YFV, Yellow fever virus; SEPV, Sepik virus; WESSV, Wesselsbron virus; EHV, Edge Hill virus; BOUV, Bouboui virus; BANV, Banzi virus; UGSV, Uganda S virus; JUGV, Jugra virus; POTV, Potiskum virus; SABV, Saboya virus; DENV-4, Dengue virus serotype 4; DENV-2, Dengue virus serotype 2; DENV-1, Dengue virus serotype 1; DENV-3, Dengue virus serotype 3; KEDV, Kedougou virus; SPOV, Spondweni virus; ZIKV, Zika virus; IGUV, Iguape virus; KOKV, Kokobera virus; AROAV, Aroa virus; BSQV, Bussuquara virus; ILHV, Ilheus virus; ROCV, Rocio virus; BAGV, Bagaza virus; SLEV, St. Louis encephalitis virus; KUNV, Kunjin virus; WNV, West Nile virus; JEV, Japanese encephalitis virus; MVEV, Murray Valley encephalitis virus; and USUV, Usutu virus. The tree was kindly provided by Dr. Edward Holmes and modified with permission.

By comparison to the vector-borne flaviviruses, relatively little is known about the NKV viruses. These viruses are most commonly found in rodents or bats, in which they do not appear to cause disease or a high viremia. NKV viruses of rodents are found only in the New World, whereas those capable of infecting bats are found in both the Old and New Worlds.²⁷⁰ Although the majority of NKV viruses (12 species) diverged with the TBFVs, two species of bat-associated viruses appear to have evolved from a lineage transmitted by mosquitoes and then lost this trait secondarily (Yokose virus [YOKV] and ENTV)^{270,434,806} (Fig. 26.1). These viruses are most similar to the *Aedes* species–vectored viruses of the YFV group. Of interest, studies with chimeric YFV and DENV engineered to express the envelope genes of Modoc virus (MODV) suggest that the host-restriction of NKV viruses may be at a postentry step of the virus life cycle.¹³⁸

Evolution

Many flaviviruses are transmitted by insect vectors, which is a unique feature of the genus not shared by the pestiviruses and hepaciviruses of the *Flaviviridae* family. One hypothesis is that flaviviruses evolved from an ancestral virus that was not vectored. Phylogenetic analysis of NS5 sequences supports this notion^{271,435}; these studies indicate that the majority of NKV viruses diverged from a lineage that gave rise to vector-borne viruses early in the evolution of flaviviruses. In this context,

MBFVs arose from the TBFV lineage. An alternative hypothesis, supported by the analysis of NS3 and complete genome sequences, is that MBFVs diverged first and then gave rise to TBFVs and the majority of NVK viruses^{73,275,274,402} (Fig. 26.1). Flaviviruses likely originated in the Old World during the last 10,000 years since the last ice age.^{160,270} All of the TBFVs, with the exception of Powassan virus (POWV), are found in the Old World.²⁷¹ POWV is found in far eastern Russia and Canada. Deer tick virus (DTV) is a subtype of POWV isolated in New England.⁸¹³ That significant speciation of POWV in the New World has not yet occurred suggests a relatively recent introduction. The most divergent MBFVs are found in the Old World.²⁷¹ The earliest lineages of the *Aedes* clade viruses are thought to originate in Africa; only DENV and YFV are now found in the New World.²⁷¹ Finally, the distribution of the NKV viruses also appears consistent with an Old World origin. Viruses that infect bats are found in either the Old or New World, whereas those associated with rodents occupy restricted niches in the New World. It is possible that bats played an important role in the introduction of these viruses into the New World.²⁴⁸

Inspection of the phylogenetic trees for MBFV and TBFVs revealed striking differences that may reflect distinct biology of the vectors that transmit them. The portion of the tree that includes the TBEV group is highly asymmetric, with a step-wise branching pattern associated with the evolutionary cline of these

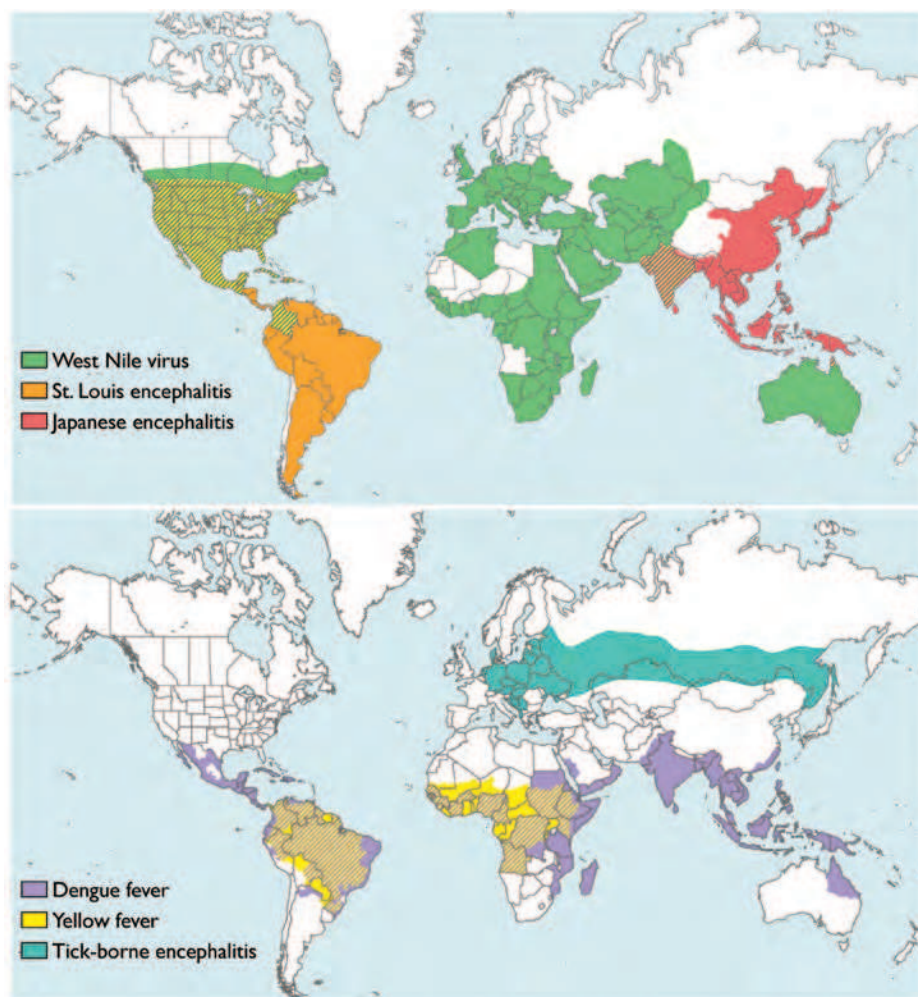

FIGURE 26.2. Global distribution of flaviviruses. The global distribution of flaviviruses with significant impact on global health.

viruses.^{910,911} In contrast, the phylogenetic tree for MBFVs is more balanced and does not result in a greater number of branches than predicted by chance. MBFVs evolution appears to involve slow phases punctuated by periods of rapid change and diversification. The last two centuries have been characterized by extensive cladogenesis (change that results in new branches on the phylogenetic tree) for the DENV and JEV complexes.

Overall, TBFVs appear to have evolved more slowly than the MBFVs (0.56 times the rate of mosquito-borne viruses).⁹¹¹ Several aspects of tick biology may limit the number of replication cycles and dispersal of TBFVs in nature that contribute to clinal pattern and modest rate of evolution: (a) ticks live for relatively long periods (2 to 7 years), (b) ticks feed only three times during their lifespan, (c) ticks may transmit viruses to other ticks during co-feeding, minimizing the importance of the vertebrate host for increasing replication cycles, and (d) ticks are relatively immobile unless carried by a vertebrate host. By comparison, MBFVs are transmitted by vectors with the capacity for wider distributions and are quickly replicated through many cycles in the mosquito vector and vertebrate hosts. MBFVs are found in overlapping distributions (e.g., the four serotypes of DENV), whereas TBFVs characteristically occupy defined and nonoverlapping niches.²⁷⁰

Global Distribution

Flaviviruses are found on six different continents where they are responsible for endemic and epidemic disease each year (Fig. 26.2). The geographic distribution of flaviviruses has proven quite dynamic, enabling emergence in new geographic areas and increased disease incidence.⁵¹⁴ For example, since its introduction into the Western Hemisphere in 1999, it took only 4 years for the WNV to spread across the United States, where it is now an endemic pathogen. The contribution of human activity toward the spread of flaviviruses is significant.²⁷¹ Prior to the development of rapid intercontinental transportation, the movement of flaviviruses between the Old World and New World was uncommon. YFV (and potentially the *Aedes aegypti* mosquito) were introduced into the Americas during the slave trade 300–400 years ago. Importation of YFV by travelers into nonendemic areas, and DENV and WNV into the New World, has been described.¹¹⁰

FLAVIVIRUS COMPOSITION AND ANTIGENIC STRUCTURE

Structure

Flaviviruses are small spherical particles composed of three structural proteins, an ~11 kb positive-sense genomic RNA, and a lipid envelope. The envelope (E) protein is a ~53 kD structural protein that functions in multiple steps of the virus life cycle including assembly, budding, attachment to target cells, and viral membrane fusion (reviewed by⁵⁹¹). The E protein is also the major target of neutralizing antibodies (reviewed by^{647,688}). The structure of the ectodomain of the E protein has been determined at the atomic level for several flaviviruses.^{557,559,591,623,647,679,918} Flavivirus E protein is an elongated, type II viral fusion protein composed of three distinct domains connected by short flexible hinges (Fig. 26.3AB). Domain I (E-DI) is an eight-stranded β -barrel located in the center of the E protein molecule. This central domain contains two of the six disulfide bonds present

in the E protein structure, as well as a site for the addition of an asparagine-linked (N-linked) carbohydrate. Domain II (E-DII) is an elongated structure that mediates dimerization of E proteins on the mature virion. A highly conserved glycine-rich loop composed of 13 amino acids located at the tip of E-DII is thought to insert into the membranes of target cells.^{10,98,558} In the context of the dimer, the E-DII fusion loop (E-DII-FL) sits in a hydrophobic pocket formed at the interface of E-DI and domain III (E-DIII). The introduction of mutations into the fusion loop blocks fusion between virions and the membranes of synthetic liposomes.¹⁶² For some flaviviruses, E-DII contains a second N-linked glycosylation site. E-DIII adopts an immunoglobulin-like fold at the carboxy-terminus (C-terminus) of the E protein ectodomain and is stabilized by a single disulfide bridge. E-DIII is the portion of the E protein that projects farthest from the surface of the mature virion and is speculated to contain binding sites for cellular factors involved in virus attachment and entry.^{71,153,455,520,679} Many of the most potent neutralizing antibodies characterized to date recognize epitopes on E-DIII (discussed below). The E protein is tethered to the viral membrane by a helical stem (the stem anchor) and two transmembrane domains.^{11,591,915}

The precursor to membrane protein (prM) is a ~20 kD protein that facilitates E protein folding and trafficking.⁵⁰¹ In addition, interactions with the E protein prevent the adventitious fusion of the virus during egress.³²¹ Virion maturation is regulated by the proteolytic cleavage of prM, which results in the formation of a “pr” protein that is ultimately released from the virion and an ~8 kD membrane-associated M peptide. The structure of the “pr” peptide has been determined at the atomic level and is composed of seven β strands held together by three disulfide bonds (Fig. 26.4A).⁴⁶⁶ prM interacts with the E protein near at the tip of E-DII adjacent to the fusion loop.^{916,917} prM is anchored into the viral membrane via two transmembrane domains.^{591,915} Recent studies suggest that antibodies specific for prM are commonly produced *in vivo*.^{61,191}

Flaviviruses assemble on virus-induced membranes derived from the endoplasmic reticulum (ER).^{353,502,513,861} Virus particles bud into the lumen of these membrane structures as immature virions on which E and prM proteins form heterotrimeric spikes that project from the surface of the virion. Within each spike, the prM protein is located at the tip of the trimer. Immature virions incorporate 60 trimers arranged with icosahedral symmetry (Fig. 26.4B).^{907,916,917} Transit of the immature virion through the mildly acidic compartments of the trans-Golgi network (TGN) triggers an extensive rearrangement of E proteins on the immature virion; the lower pH induces a structural transition such that E proteins lie flat as antiparallel dimers on the surface of the virion, analogous to the structure of the mature virion discussed below.⁹⁰⁷ Under acidic conditions, prM remains associated with the fusion loop on this structure and protrudes from the surface of an otherwise smooth virus particle. This pH-dependent conformational change increases the susceptibility of prM for a furin-like serine protease.⁷⁷⁷ Cleavage of prM is the hallmark of the virion maturation process, and is a required step in the virus life cycle.²²³ Release of the virion into the neutral conditions of the extracellular milieu results in the dissociation of the pr peptide.^{466,907} Mature virions are relatively smooth virus particles that incorporate 180 copies of the E protein arranged with an unusual herringbone pseudo-T = 3 icosahedral symmetry^{425,590,591} (Fig. 26.5A).

FIGURE 26.3. Structure of the flavivirus E protein.

The envelope (E) proteins of flaviviruses are elongated class II viral fusion proteins composed of three structurally distinct domains. **A:** Ribbon diagram of the Dengue virus (DENV) E protein dimer as seen from the top; individual domains of each E protein monomer are indicated (domain I, E-DI, red; domain II, E-DII, yellow; and domain III, E-DIII, blue). The fusion loop at the tip of E-DII is shown in green. **B:** DENV E protein as viewed from the side. The stem anchor connecting the E protein to the viral membrane is not shown. The two N-linked carbohydrate modifications at positions Asn67 and Asn154 are shown. **C:** Structure of the West Nile virus (WNV) E-DIII highlighting amino acids that form the epitope recognized by the type-specific neutralizing mAb E16. Residues identified in structural studies as antibody contacts are shown in brown; the side chains of residues demonstrated to be critical for antibody binding are shown and labeled. **D:** Structure of the DENV E-DIII highlighting the epitope recognized by the group-reactive mAb 1A1D-2. Residues identified in structural studies as antibody contacts are shown in brown; the side chains of residues demonstrated to be critical for antibody binding are shown and labeled. We thank Mr. Phong Lee (National Institute of Allergy and Infectious Diseases [NIAID], National Institutes of Health [NIH]) for preparation of the figure.

FIGURE 26.4. The immature flavivirus virion. The structure of prM and the immature flavivirus virion. **A:** Ribbon representation of the Dengue virus (DENV) pr peptide complexed with the DENV E protein. The pr peptide is shown in cyan. Domains I, II, and III of the E protein are shown in red, yellow, and blue, respectively. **B:** Surface-shaded representation of the immature DENV virion at neutral pH. **C:** Cryo-electron microscopy visualization of extracellular DENV reveals the heterogeneity of virions released from mosquito cell cultures. Immature (I) and mature (M) virions are indicated. Partially mature virions (P) characterized by the appearance of smooth and spiky features on the same virion comprise a significant fraction of the virions released from cells.

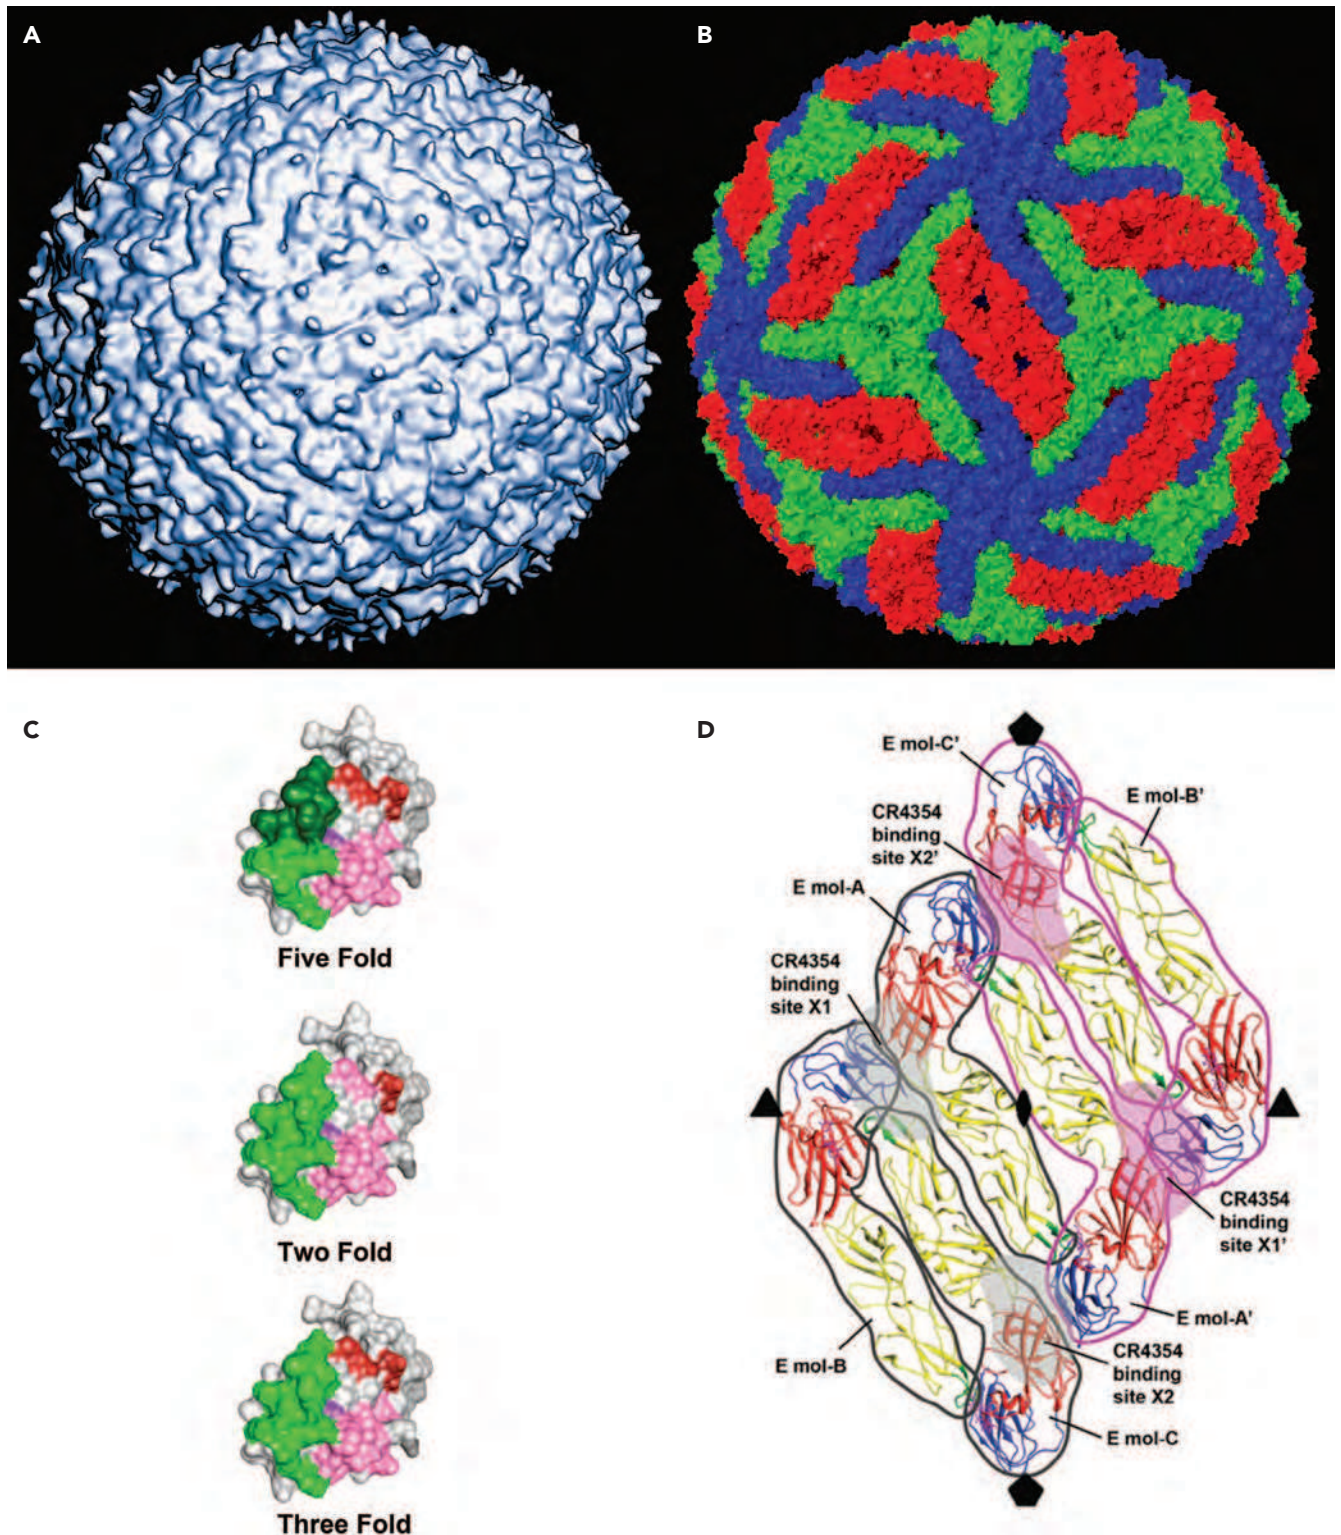

FIGURE 26.5. The arrangement of E proteins on the mature flavivirus increases the complexity of the antigenic surface of the virus particle. **A:** Structure of the mature DENV virion. **B:** Structure of the mature virion highlighting the association of E proteins proximal to the two-, three-, and five-fold symmetry axis of the virion, shown in *red*, *green*, and *blue*, respectively. **C:** Epitope accessibility varies as a function of the location of a particular E protein on the surface of the pseudo-icosahedral mature virion. Residues important for the binding of mAb E16 are highlighted in *green* for E proteins of each symmetry environment. The steric conflicts that prevent binding of E16 to E proteins proximal to the fivefold symmetry axis are shown in *dark green*. Accessibility of amino acids involved in 1A1D-2 binding are shown in *pink*; steric conflicts that prevent binding to E proteins on the mature virion are shown in *red*. **D:** The complex epitope of mAb 4354 composed of multiple E proteins is shown. Individual domains of each E protein monomer are indicated (domain I, E-DI, *red*; domain II, E-DII, *yellow*; and domain III, E-DIII, *blue*).

Each virion is composed of 30 sets of three antiparallel dimers. In this configuration, E proteins exist in one of three chemically distinct dimer environments defined by their proximity to the two-, three-, or fivefold symmetry axis (Fig. 26.5B).

The Antigenic Surface

Flaviviruses were first classified according to serologic reactivity.^{127,188} These early studies generally agreed with approaches that group viruses as a function of genetic relatedness (discussed above, Fig. 26.1).⁵²² Flavivirus-reactive antibodies are classified as a function of their capacity to discriminate between the antigens of viruses within and between related serologic groups of viruses.⁸²⁹ For example, monoclonal antibodies that react with DENV may be type-specific (a single DENV serotype), subcomplex-specific (more than one DENV serotype), complex reactive (all DENV viruses), or flavivirus-group reactive (multiple flaviviruses).³²² Type-specific mAbs provided a rapid and specific method for distinguishing between antigenically related viruses.^{324,572} Furthermore, recent studies indicate that antibodies differentially recognize different genotypes within a given serotype.^{99,751,852}

E Protein Epitopes Recognized by Neutralizing Antibodies

The majority of neutralizing antibodies bind epitopes on the E protein (reviewed in⁶⁸⁸). Early studies distinguished epitopes on the E protein based on the biochemical and functional properties of mAbs including a capacity to bind and compete for viral antigens, neutralize virus, and inhibit hemagglutination of red blood cells.^{251,319,322,394,395,411,642,690} An early model of the antigenic structure of the E protein was proposed by Heinz and colleagues that featured three nonoverlapping antigenic domains (A, B, and C); more refined clusters of epitopes within each domain were based on functional differences.^{286,318} These studies also identified a small number of antibodies that bound the E protein outside of these domains. This advance not only provided a framework to classify antibodies based on their epitope, but also provided context to consider relationships between epitope location and the functional properties of mAbs.⁶⁸⁹ Antigenic domain A epitopes were recognized by cross- and group-reactive antibodies, domain B epitopes were typically type specific, and domain C epitopes were recognized by subtype-specific mAbs.^{286,521} These epitopes were subsequently shown to correspond to E-DII, E-DIII, and E-DI, respectively.⁶⁷⁹

All three domains of the E protein are recognized by neutralizing antibodies, albeit with widely varying potency. Epitopes of some of the most well-characterized antibodies to date are described below, although it should be anticipated that this list will expand as greater insight to the complexity of the antigenic surface of the virion is obtained:

E-DIII-LR

Many of the most potent neutralizing antibodies characterized to date bind epitopes on E-DIII. Potently neutralizing antibodies that bind an epitope on the domain III lateral ridge (E-DIII-LR) of several flaviviruses have been identified.^{52,150,170,279,627,647,689,708,751} mAb E16 is a type-specific WNV-reactive mAb that neutralizes at picomolar concentrations *in vitro* and protects mice from lethal challenge when administered 5 days after infection.^{581,582,627,648} The structure of E16

bound to E-DIII has been determined and revealed a binding footprint composed of four discontinuous loops centered on amino acids of the BC loop and amino-terminal region (positions 306, 307, 330, and 332)⁶²⁴ (see Fig. 26.3C). Type-specific neutralizing antibodies against DENV-2 have been mapped to an epitope composed of multiple regions of the upper lateral surface of E-DIII, including the FG loop.^{279,360,380,794,795} The binding of many of these antibodies to DIII is also sensitive to amino acid substitutions on the BC loop, C-C' loop, the amino-terminal region (residue 301), or the A-strand (e.g., residue 304); the latter structure is also recognized by antibodies that neutralize DENV with subcomplex specificity, as discussed below. For example, the highly characterized mAb 3H5 recognizes an epitope composed of residues on both the FG loops and the A strand.⁷⁹⁵ Mapping experiments with type-specific DENV-1,⁷⁵¹ DENV-3,^{99,852} JEV,⁸⁹¹ and TBEV⁷⁸⁶ antibodies have identified similar epitopes.

E-DIII A-STRAND

Antibodies with a pattern of complex and subcomplex reactivity have been mapped to the A-strand of E-DIII.^{497,671,795,824} mAb 1A1D-2 potently neutralizes DENV-1, DENV-2, and DENV-3, but fails to bind DENV-4 viruses. The structure of mAb 1A1D-2 bound to E-DIII was solved and revealed that this antibody binds an epitope on the A strand and is sensitive to mutation of DENV residues 305, 307, and 310 (see Fig. 26.3D).⁴⁹⁷ In addition, these studies identified residues in the G strand that play a role in antibody binding, consistent with mapping studies of other complex- and group-reactive antibodies.^{280,489,751,824}

E-DII-FL

Antibodies that bind the fusion loop of E-DII are highly cross-reactive.^{168,171,629,787} Although mutation of conserved fusion loop residues reduces antibody binding, other adjacent structures also may contribute to the fine specificity of antibody binding and the functional properties of these antibodies.^{266,629} The structure of the WNV fusion loop-reactive antibody mAb E53 bound to soluble E proteins has been determined.¹⁴⁹ Residues shown to be important antibody contacts include those of the fusion loop (residues 104–107, and 109–110) as well as residues of the BC-loop of E-DII.⁶²⁹ The fusion loop epitope is also poorly accessible on the mature virion, as discussed in detail below.^{629,787}

E-DI

Antibodies that bind E-DI have also been characterized. mAb 5H2 is a type-specific antibody that neutralizes DENV-4. Neutralization escape studies mapped 5H2 binding to an epitope that includes residue 174 of E-DI.⁴⁴⁵ DI-reactive antibodies that bind WNV (E121; residues 175, 191, 193, and 194), DENV2 (mAb DV2–48, residue 177), and TBEV (IC3 and i2, residues D181 and K171, respectively) also have been characterized.^{338,521,629,794} The recently described WNV mAb CR4354 that binds a complex epitope that includes the linker between E-DI and E-DII will be described in detail below.³⁸⁴

Antibodies That Bind the prM Protein

Antibodies that react with the prM protein have been described.^{61,121,191,229,844} Generally, these antibodies are characterized by low neutralizing activity *in vitro*. Recent studies suggest that anti-prM antibodies are elicited frequently *in vivo*,

and may contribute to the pathogenesis of DENV infection as discussed below.^{191,685} Human monoclonal antibodies to WNV prM protein have been isolated and mapped to residues V19, T20, T24, and L33.¹²¹

Complexities of Antibody Recognition of the Virion

The complex and dynamic arrangement of the E proteins on the surface of flaviviruses complicates an understanding of how antibodies interact with flaviviruses. E proteins exist on the mature virus particle in different chemical environments (Fig. 26.5B; defined in relation to the two-, three-, and five-fold symmetry axes of the pseudo-icosahedral particle), which impacts antibody recognition. Amino acids involved in antibody recognition may be differentially accessible for antibody binding depending on their location on the virus particle.^{624,629,787} As mentioned above, the WNV mAb E16 binds a cluster of residues on the upper lateral surface of E-DIII.⁶²⁴ However, this epitope is not uniformly accessible for antibody binding on all E proteins on the mature virus; steric constraints imposed by the tight packing of E-DIII on E proteins at the fivefold axis of symmetry prevent antibody binding to these molecules (Fig. 26.5C).^{383,624} Therefore, although the mature virion incorporates 180 copies of the E protein, a maximum of 120 antibodies physically can bind the virus particle. This is not an unusual feature of this antibody as none of the antibodies studied to date using structural methods appear capable of binding all E proteins on the intact mature virus particle. In fact, the molecular basis for recognition by many antibodies cannot be explained using static models of virion structure.

EPITOPES CAN BE COMPOSED OF MORE THAN ONE PROTEIN ON THE SURFACE OF THE VIRION

Virions contain 180 individual E proteins. To date, most of the well-characterized antibodies are capable of binding monomeric E proteins, indicating their epitopes are composed of residues contained within a single E protein molecule. However, complex epitopes composed of contact residues from adjacent E proteins have been described.^{168,384,521} mAb CR4354 is a human antibody that binds the hinge between E-DI and E-DII. Mapping studies using recombinant forms of the E protein failed to identify the CR4354 epitope because this antibody was unable to bind soluble forms of the E protein. A loss-of-function substitution at position K136 was defined by neutralization escape studies.⁸⁵⁰ Cryoelectron microscopic reconstructions of CR4354 Fab fragments bound to the mature virion revealed a complex epitope composed of residues on neighboring E proteins (Fig. 26.5D).³⁸⁴

INCOMPLETE VIRION MATURATION IMPACTS ANTIBODY-MEDIATED NEUTRALIZATION

Cleavage of prM is a required step in the flavivirus life cycle; mutation of the RRXR/S motif in prM recognized by furin-like proteases renders TBEV noninfectious.²²³ However, biochemical analysis of preparations of flaviviruses released from cells indicated that a substantial amount of prM may remain uncleaved. Recent studies demonstrate that more than 90% of DENV virions could be precipitated with anti-prM antibodies.³⁶⁸ Electron microscopy studies identified virus particles with structural features of both mature and immature virions (hereafter referred to as “partially mature virions”) (Fig. 26.4C).⁶⁵³

Several lines of evidence suggest that partially mature virions are infectious. Virions produced in the presence of ammonium chloride display a reduced sensitivity to inactivation when exposed to acid, presumably because pH-mediated changes in the conformation of E protein are reversible when complexed with prM.²⁸⁵ In addition, the carbohydrate on prM can mediate attachment of the lineage II 956 strain of WNV (which lacks an N-linked carbohydrate on the E protein) onto cells expressing the c-type lectin CD209L.¹⁸³ Although these studies demonstrate that virions containing prM may be infectious, the stoichiometric requirements of prM cleavage have not yet been determined.

The presence of partially mature secreted virions impacts antibody recognition in at least two ways. Increasing the efficiency of virion maturation resulted in a marked reduction in the sensitivity of WNV to neutralization by antibodies that bind several structurally distinct epitopes, including the DI-LR and DII-FL epitopes recognized by mAbs E121 and E53, respectively.⁶⁰⁷ Conversely, decreasing the extent of virion maturation enhanced neutralization by these mAbs. An analysis of the sensitivity of polyclonal antibody elicited by vaccination with two distinct candidate WNV vaccines revealed maturation state-dependent changes in neutralization potency in roughly half the volunteers.⁶⁰⁷ The structural basis for this pattern of recognition has been investigated.¹⁴⁹ mAb E53 does not efficiently bind the E protein on mature virions due to poor accessibility of the fusion loop epitope on the mature virus particle. In addition to modulating the potency of neutralizing antibodies, uncleaved prM on infectious virus particles may interact directly with antibodies, resulting in enhanced infection of Fcγ-receptor bearing cells *in vitro* and *in vivo* as discussed below.^{61,191,347,685,912}

IMPACT OF STRUCTURAL DYNAMICS OF THE VIRUS PARTICLE

Flaviviruses present a complex and dynamic antigenic surface to the immune system that is not fully captured by the static models of virion structure. It has long been appreciated that proteins are in constant motion and sample an ensemble of conformations at equilibrium.⁸⁴ Proteins incorporated into virus particles also are structurally dynamic.^{361,888} Virus “breathing” has been demonstrated for several unrelated classes of viruses,^{88,459} and may affect antibody recognition.^{467,905} As an example, the accessibility of the A-strand epitope on the mature virion is limited by steric constraints arising from the arrangement of E proteins on the virus particle. The binding of Fab fragments of the subcomplex-reactive A-strand-specific mAb 1A1D-2 to mature DENV virions was shown to be temperature dependent; significant Fab binding was observed only after incubation at 37°C.⁴⁹⁷ Cryoelectron microscopic reconstruction of mature DENV bound by the 1A1D-2 Fab revealed significant changes in the arrangement and orientation of E proteins on the surface of the virus particle. These results suggested that the binding of 1A1D-2 stabilized the E proteins in a state distinct from the herringbone arrangement found on mature virions. More recent studies suggest the impact of viral dynamics on antibody-mediated neutralization is widespread among antibodies of differing specificity. Analysis of the neutralizing activity of a panel of mAbs specific for structurally distinct epitopes revealed a time- and temperature-dependent aspect of neutralization of WNV and DENV attributed to changes in epitope accessibility arising from the dynamic

motion of E proteins on the virion.²¹⁰ Given sufficient time, even epitopes that are poorly accessible in all three symmetry axes of the mature virion may support some level of neutralization. The scope of the structural conformations sampled by flaviviruses at equilibrium is not yet understood. Changes in the configuration of E proteins on dynamic virions have the potential to affect several aspects of antibody binding (functional affinity, bivalency, antibody binding orientation), and thus, complicates our understanding of the antigenic surface of the flavivirus virion.

Antibodies to NS1 Can Protect *In vivo*

NS1, a protein that is absent from the virion, is secreted at high levels into the extracellular environment during flavivirus infection, predominantly as a hexamer,²³⁸ with significant accumulation (up to 50 µg/ml) in the sera of DENV-infected patients.^{6,28,470,906} In addition, soluble NS1 can bind back to the plasma membrane of cells through an interaction with specific sulfated glycosaminoglycans.²⁹ Furthermore, NS1 is expressed directly on the surface of infected cells, possibly via glycosyl phosphatidyl inositol (GPI) linkage,³⁵⁴ lipid raft association,⁶²¹ or through an as-yet undefined mechanism. Several groups also have generated nonneutralizing, yet protective mAbs against NS1.^{155,156,194,230,323,665,720,721,723-725} Therefore, protection against flavivirus infections *in vivo* does not always correlate with neutralizing activity *in vitro*.^{93,690,722} Beyond direct virus neutralization, antibody binding to virions or virus-infected cells can trigger protective Fc-dependent antiviral activities through complement activation or Fc-γ receptor-mediated immune complex clearance mechanisms. Fc-γ receptors can activate or inhibit immune responses depending on their cytoplasmic domain and association with specific signaling molecules.⁶¹⁷ A requirement for Fc effector function has been established for protective anti-NS1 mAbs. NS1 is expressed on the cell surface or secreted into the extracellular space and antagonizes complement control of flavivirus infection by binding the negative regulator factor H or by promoting C4 degradation.^{24,154} Passive transfer of mAbs against NS1 can protect mice against lethal infection by WNV and YFV,^{155,722} and this requires an intact Fc moiety.⁷²⁵ Mechanistic studies using immunodeficient mice demonstrate that protective anti-NS1 mAbs recognize cell surface-associated NS1 and trigger Fc-γ receptor-dependent phagocytosis and clearance of WNV-infected cells.¹⁵⁶

CLINICAL AND PATHOLOGIC SYNDROMES OF THE FLAVIVIRUSES

DENGUE VIRUS

History, Global Distribution, and Epidemic Cycle

The natural cycle of epidemic Dengue virus (DENV) infection is between the mosquito vector (*Aedes albopictus* or *Aedes aegypti*) and humans (Fig. 26.6). After mosquito inoculation, DENV infection causes a spectrum of clinical disease ranging from self-limited Dengue fever (DF) to a life-threatening hemorrhagic and capillary leak syndrome (Dengue hemorrhagic fever [DHF]/Dengue shock syndrome [DSS]). Globally, there is significant diversity among DENV strains, including four distinct serotypes (DENV-1, DENV-2, DENV-3, and DENV-4) that differ at the amino acid level in the viral envelope proteins by 25% to 40%. DENV causes an estimated 25 to 100 million infections and 250,000 cases of DHF/DSS per year worldwide, with 2.5 billion people at risk.^{298,562}

Although a dengue-like syndrome may have occurred in China several times during the first millennium AD, the initial description of a DENV epidemic is attributed to Benjamin Rush, a physician in Philadelphia, in his article reporting a febrile outbreak in 1780.⁶⁹⁴ Primary DENV infection and epidemics were common in North America, the Caribbean, Asia, and Australia during the 18th and 19th centuries, presumably due to the widespread ecology of the mosquito vectors. During World War II, DENV spread to and through Southeast Asia. Troop movement and the destruction of the environment and human settlements are believed to have promoted the spread of DENV and their mosquito vectors throughout Southeast Asia and the Western Pacific.⁴³³ Since 1950, the number of people infected has risen steadily, such that today DENV is the leading arthropod-borne viral disease in the world. With the spread and co-circulation of multiple DENV serotypes, secondary infection with heterologous serotypes and epidemic DHF/DSS emerged 50 years ago in Southeast Asia,³¹⁰ and more recently in the Americas in 1981⁴²⁰ and South Asia in 1989.⁵⁵¹ Since the 1950s, epidemics involving thousands of people with multiple DENV serotypes and strains occur annually in multiple parts of the world, including the Americas, Asia, Africa, and Australia, in essence wherever the primary mosquito vector *Aedes aegypti* is present. Indeed, after a recent outbreak of DENV

FIGURE 26.6. Life cycle of Dengue virus (DENV). DENV circulates in nature in two relatively distinct transmission cycles vectored by *Aedes* sp. mosquitoes. DENV infection of humans results in a sufficiently high viremia to support infection of feeding mosquitoes; transmission cycles of DENV do not require an enzootic amplifying host. DENV may also replicate in a sylvatic cycle. Although incompletely understood, the contribution of sylvatic strains of DENV to human infections appears minimal.

in Key West Florida in 2009, a serosurvey conducted by the Centers for Disease Control and Prevention (CDC) reported that 5.4% of households had evidence of recent DENV infection.¹ As a reflection of this, the global incidence of DHF/DSS has increased more than 500-fold, with more than 100 countries affected by outbreaks of dengue.⁴⁴²

DENV Diversity

Globally, there is significant diversity among DENV strains. The four serotypes of DENV (DENV-1, DENV-2, DENV-3, and DENV-4) are genetically distinct but cause similar diseases and share epidemiologic features. All DENV strains are members of the Dengue antigenic complex; inclusion of a strain as DENV is based on antigen cross-reactivity, sequence homology, and genome organization.¹²⁰ The four serotypes of DENV were historically distinguished by limited cross-neutralization or hemagglutination inhibition using serum from infected individuals. Subsequent sequencing analysis revealed that individual serotypes of DENV can differ from one another at the amino acid level significantly, with 30% to 40% variation in the viral envelope proteins. However, within a given serotype, amino acid homology is much greater, with conservation levels at approximately 90% or higher. Therefore, individual DENV serotypes (e.g., DENV-1 versus DENV-4) vary far more than distinct viruses in Japanese encephalitis serocomplex (e.g., WNVs and JEVs vary by 10% to 15% at the amino acid level), which has led some to consider DENV as a group of four different viruses that are linked by serology, epidemiology, and disease pathogenesis. Differences in severity associated with individual serotypes or particular sequences of serotypes in sequential infection have been observed, and it still is unclear whether some serotypes are inherently more pathogenic than others. DENV-2 viruses have been commonly associated with DHF/DSS,^{36,112,821} as are DENV-1 and DENV-3 viruses.^{273,314,551} In comparison, DENV-4 appears more commonly to be clinically mild, although it can cause severe disease.⁶¹⁹

Genetic variation of DENV, however, is not limited to serotype. Geographic variants within a serotype were initially identified by RNase fingerprint assays.^{678,847} Subsequently, nucleic acid sequencing confirmed differences within each serotype, allowing for classification of genotypes that vary further by up to approximately 6% and 3% at the nucleotide and amino acid levels, respectively.^{337,681} DENV genotype classification was originally defined by sequence variation within a given genomic region (e.g., *E* and *NS1* genes). More recent analysis has used high-throughput full genome sequencing technologies to assign phylogenetic classification. Although there remains some dissonance among investigators, most classification schemes include five DENV-1 genotypes, four or five DENV-2 genotypes, four DENV-3 genotypes, and two or three DENV-4 genotypes.^{682,874} Beyond serotype and genotype, two further types of DENV complexity should be mentioned: strain variation and quasispecies. DENV strain variation refers to the limited change that occurs among individual isolates; this was classically described as within a serotype, although as DENV continues to emerge and evolve, variation now occurs within a genotype. Strain variation within a genotype may be functionally important, as it can affect antibody neutralization, presumably due to changes at key sites within exposed epitopes.^{99,794,852,925}

In addition to serotype, genotype, and strain variation, DENV has the capacity to accumulate variation rapidly within

an individual host. Viral quasispecies comprises a cloud of variants that are genetically linked through mutation. It is observed during infection by many RNA viruses (e.g., hepatitis C virus [HCV], human immunodeficiency virus [HIV], and influenza) and creates diversity that allows a viral population to adapt rapidly to dynamic environments and evolve resistance to immune responses, vaccines, and antiviral drugs.^{450,848} DENV exists as a collection of highly similar variants forming a quasispecies⁸⁶⁹ by virtue of its error-prone NS5 polymerase, which has an estimated mutation rate of 10^3 to 10^5 substitutions per nucleotide copied per round of replication.^{137,836} Preliminary studies suggest that genetic diversity is greater in the structural proteins, which may have less constraint to maintain integral functions. The study of genetic and intrahost diversity for DENV is still in its relative infancy, and thus more analysis is warranted to define how mutation and variation impact fitness, tropism, and resistance.

Clinical Features of Acute DF: Primary DENV Infection

DENV infection of humans after mosquito inoculation causes a spectrum of clinical disease ranging from inapparent disease (~50% of infections^{37,112,224}), self-limited dengue fever (DF) to severe DHF and DSS. A classical presentation of DF is an abrupt onset of a debilitating febrile illness characterized by headache, retroorbital pain, myalgias, arthralgias, and a maculopapular rash that occurs after a 2- to 7-day incubation period after mosquito inoculation.⁷⁰⁰ Some individuals experience severe bone and joint pain (“break-bone fever”) and develop petechial hemorrhages that are associated with mild to severe thrombocytopenia. There is no specific constellation of signs or symptoms to differentiate DF from other acute flu-like viral syndromes, so a health care provider must have a high index of suspicion for diagnosis in the setting of the appropriate epidemiology. DF also may present in a less classical form as an undifferentiated febrile illness with rash along with mild upper respiratory symptoms (cough, pharyngitis, rhinitis), particularly in children. DF is usually self-limited, lasting 1 to 2 weeks, although some (up to 25% of hospitalized patients) experience a prolonged postinfectious fatigue and depression syndrome that can persist for weeks, akin to that seen after Epstein-Barr virus (EBV) infection and mononucleosis.⁷³⁹ Because of the debilitating fever and musculoskeletal symptoms, the morbidity toll is high in clinically apparent DF, whereas the mortality rate is exceedingly low. Primary DF usually occurs during the initial DENV infection of an individual, with the exception of infants from immune mothers that have acquired antibodies transplacentally.

Clinical Features of DHF/DSS: Secondary and Infant DENV Infection

The incidence of the most severe form of DENV disease, DHF/DSS, varies considerably between primary and secondary infections. A secondary DENV infection results when a person previously infected with one serotype is exposed to a different serotype, and is the single most important risk factor for severe dengue disease.^{112,224,294,305} Epidemiologic data in Thailand has shown greater than 10-fold higher rates of DHF/DSS during secondary compared to primary infection of children.⁸⁴³ It should be pointed out that even during secondary infection, DHF/DSS is quite rare, with only 0.5% of

secondary infections progressing to the most severe forms of dengue disease. DHF/DSS is characterized by rapid onset of capillary leakage accompanied by thrombocytopenia and mild to moderate liver damage, reflected by increases in serum levels of hepatic enzyme (e.g., aspartate aminotransferase [AST] and alanine aminotransferase [ALT]).³⁰¹ DHF/DSS usually occurs as a second phase of the illness, after a short period of deferescence from the initial fever. Hemorrhagic manifestations are observed in a subset of DHF/DSS cases and include petechiae, epistaxis, gastrointestinal bleeding (hematemesis or melena), menorrhagia, and a positive tourniquet test. Use of the term hemorrhagic fever instead of dengue capillary-leak syndrome has led many to anticipate that bleeding is the greatest threat. Rather, fluid loss into tissue spaces with hemoconcentration and hypotension can result in shock, which carries the highest risk of mortality.⁶¹² From a diagnostic standpoint, an elevated hematocrit and upper abdominal ultrasonogram showing a thickened gall bladder wall, hepatomegaly, ascites, or pleural effusions are evidence of fluid shifts associated with a capillary leak syndrome.

Whereas DHF/DSS occur largely after secondary infection by a different DENV serotype in children and adults,²⁷³ in infants younger than age one born to dengue-immune mothers, primary infection can cause severe DHF/DSS.^{305,356,764} In clinical studies, maternal anti-DENV neutralization antibody titers and age of the infant correlated with disease. The actual age at which DHF/DSS occur in infants (peak at 7 months) corresponds to the age at which maximum enhancing activity for DENV infection in primary monocytes is observed *in vitro*.⁴⁰⁵ Severe clinical manifestations of DHF/DSS are more prevalent in infants³¹¹ and there is an approximately fourfold higher mortality rate compared to other age groups.³⁷³ Infants represent approximately 5% of children hospitalized with DHF/DSS in many parts of Southeast Asia.^{140,273,303} The more prevalent or severe clinical manifestations associated with infant DHF/DSS include seizures, hepatic dysfunction, thrombocytopenia, high-grade fever, diffuse rash, peripheral edema, ascites, and frank shock.³⁵⁶

Although it is not fully accepted by the field, some clinical studies have suggested that severe DENV infection also can have neurologic manifestations including transverse myelitis, Guillain-Barre syndrome, encephalitis, and encephalopathy,^{769,841} occurring in as many as 1% to 6% of DHF/DSS cases.^{122,325} In contrast to other encephalitic flaviviruses (e.g., JEV, WNV, or tick-borne encephalitis viruses), DENV historically has not been considered as neurotropic. However, the discovery of DENV and anti-DENV immunoglobulin M (IgM) in the cerebrospinal fluid of patients with encephalopathy suggests that it may be capable of causing central nervous system (CNS) infection as part of a severe DHF/DSS syndrome, at least in a subset of individuals.^{507,769} In support of this, focal imaging abnormalities have been detected in brain MRI scans of DENV-infected patients.^{122,872} Although these results are suggestive, bona fide DENV encephalitis and CNS disease may not be fully accepted until its antigens are reliably detected in the brains of encephalopathic patients and a more complete understanding of the molecular determinants for neurotropism is acquired.

Pathologic Features of DHF/DSS

Although DENV is the leading mosquito-borne transmitted viral infection in the world, there are few detailed autopsies

series of patients who succumbed to DHF/DSS, and fewer performed with newer molecular techniques and markers. Detailed histopathologic studies that might inform a basic understanding of DENV pathogenesis are rare because much of the lethal disease occurs in regions lacking sophisticated laboratory infrastructure, highly trained personnel, and repositories for long-term tissue storage. Forensic studies also are complicated by lack of standardization of histologic procedures and variation in the quality of specimen preparation and storage.

A recent summary of the autopsy literature from a total of 160 fatal DHF/DSS cases occurring primarily in children and adolescents was published.⁵³¹ Pathologic findings in the liver of DHF/DSS cases include centrilobular necrosis, changes in fatty tissue, inflammatory leukocyte infiltration, and Kupffer cell hyperplasia.^{70,113} Gross macroscopic examination revealed multiple hemorrhagic foci. Microscopic analysis has shown increased inflammatory infiltrates around the portal vessels, sinusoidal congestion, small hemorrhages, midzonal hepatocyte necrosis, and microvesicular steatosis.^{228,293} In other tissues (spleen or lung) hemorrhage, tissue edema, and plasma leakage have been observed.⁵⁰

A key to understanding the pathogenesis of severe DENV infection is defining cellular tropism of infection, which could influence the host inflammatory response that results in the capillary leakage syndrome. Autopsy series have shown the presence of DENV antigen or nucleic acid in cells of the skin, liver, spleen, lymph nodes, kidney, lung, thymus, or brain.^{38,50,165,293,377,392,553,692} However, several of these studies used *in situ* hybridization or reverse transcriptase polymerase chain reaction (RT-PCR) based assays, and thus have not definitively shown that infectious virus is produced in a given cell of a target tissue. In severe DENV cases, infectious virus can be reliably isolated from blood, lymphoid tissues, and the liver, although the cellular source of the virus remains controversial. Studies in humans, nonhuman primates, and small animal models support a role for infection of myeloid cells (blood monocytes, tissue macrophages, Kupffer cells), and possibly other cells including hepatocytes²⁹⁶ and endothelial cells.^{50,912}

YELLOW FEVER VIRUS

History, Global Distribution, and Epidemic Cycle

Several recent excellent reviews have described the epidemiology and historical details of yellow fever virus (YFV) infection.^{41,222,246} YFV, the causative agent of yellow fever virus (YFV), was first isolated (strain Asibi) in 1927 after inoculation of a rhesus monkey with the blood of a patient from Ghana.⁷⁸⁹ YFV originated in Africa, was imported into the Americas during the slave trade, and had the first reported epidemic in the Yucatan in 1648.⁴⁵ Historically, large epidemics of YF disease occurred beyond these regions and were described in the 17th through 20th centuries as far north in the Americas as Canada, as well as in parts of Europe including Spain, Italy, France, and England.⁵⁶⁶ Despite the presence of an effective vaccine (17D strain) that was developed in 1937 by Max Theiler and colleagues,⁸²⁰ with more than 500 million doses administered to humans,²⁴⁶ YFV infection has remained a public health threat in restricted parts of the world. Currently, YFV is endemic in the tropical regions of Africa and the Americas, infects humans and

nonhuman primates, and is transmitted by mosquitoes including *Aedes aegypti*. The World Health Organization (WHO) estimates an incidence of 200,000 cases per year, leading to about 30,000 deaths, with the majority occurring in sub-Saharan Africa.⁸⁹⁰ Overall, 44 countries in Africa and the Americas are considered within the modern YFV endemic zone, with almost 900 million people at risk of infection.^{222,246}

The sylvatic or jungle cycle of YFV in which transmission occurs between mosquitoes and wild monkeys explains why extensive vaccination campaigns have reduced but not eradicated infection. In East Africa, YFV infection is maintained enzootically in monkey transmission cycles in the jungle with the *Aedes africanus* mosquito vector. Periodically, infection may cross into humans during an intermediate savannah cycle, with transmission by several different *Aedes* mosquito species (e.g., *Aedes bromeliae*). Indeed, in the Americas, most cases appear to be a result of humans intruding on the jungle cycle of YFV.⁴⁷ Epidemic YFV infection (human–mosquito–human cycle) ensues in urban or domestic areas with *Aedes aegypti* as the principal mosquito vector. Rapid urbanization in Africa and the Americas with population shifts from rural to urban settings combined with the collapse of mosquito eradication programs has allowed the *A. aegypti* vector to repopulate many parts of the world, and caused YFV to be classified as a reemerging threat for humans.²⁴⁶

YFV Diversity

YFV does not belong to an antigenic subgroup based on plaque reduction neutralization assays,¹²⁰ but shows greater genetic relationship to other African flaviviruses including Banzai, Zika, Wesselsbron, and Bouboui viruses. Indeed, cross-protection against YFV infection in monkeys has been shown after immunization with some of these related viruses.³²⁶ Although there is only one serotype of YFV, there is significant diversity within the genus. Seven genotypes have been proposed including two West African genotypes, a single Central/South African genotype, two East African genotypes, and two South American genotypes.²²² These genotypes of YFV were originally defined based on nucleotide variation of greater than 9% in the prM, E, and 3' UTR gene regions^{601,858} and have been confirmed with full-genome sequencing of YFV isolates.⁸⁵¹ Phylogenetic studies suggest that YFV originated in East or Central Africa and was introduced subsequently into West Africa and South America.^{600,601} Beyond genotypes, sequence analysis of 79 YFV strains isolated from 1935 to 2001 in Brazil revealed further strain divergence into clades that differ at the nucleotide and amino acid level by up to 7% and 5%, respectively.⁸⁴² The physiologic basis for genotype-specific amino acid variation between YFV isolates remains uncertain, although it is likely that selection confers a phenotypic advantage in a given host.

Clinical Features of YFV Infection

In humans, YFV infection causes a variable clinical syndrome ranging from no symptoms, to mild febrile flu-like illness, to fulminate and possibly fatal disease. Approximately 15% of people who become infected develop severe visceral disease, and in this group there is a 20% to 50% case fatality rate.⁵⁶⁴ Symptoms occur within 3 to 6 days of mosquito inoculation and include an abrupt onset of fever, chills, myalgia, back pain, and headache or the first “period of infection,” which usually lasts 3 days and corresponds to peak viremia. During

this phase, individuals are infectious to mosquitoes. In some, this stage may be followed by a short “period of remission,” with defervescence and improvement of clinical signs and symptoms. Shortly after, in a subset (20%) of patients, fever and symptoms worsen (“period of intoxication”) with vomiting, epigastric pain, and jaundice (which gives yellow fever its name); this is associated with YFV replication in the liver, an absence of viremia, and measurable anti-YFV antibodies in serum. As time progresses, severe YFV infection evolves into a hemorrhagic fever characterized by severe hepatitis, renal failure, hemorrhage, shock, and multiorgan failure. A bleeding diathesis manifests with melena, hematemesis, epistaxis, ecchymosis, menorrhagia, petechial hemorrhages, and blood oozing from mucous membranes. Renal failure is associated with an abrupt decrease in urine output and with albuminuria. Laboratory tests show leukopenia, thrombocytopenia, and a coagulopathy. Death occurs on the 7th to 10th day of illness and is preceded by hemodynamic and cardiovascular instability, acute liver failure, hypothermia, hypoglycemia, and coma. For those individuals surviving severe YFV infection, convalescence is prolonged with hepatitis and associated constitutional symptoms persisting sometimes for months.

Pathologic Features of YFV Infection

Macroscopic gross pathology of tissues from YFV infection autopsy studies show an enlarged and icteric liver and edematous and enlarged kidneys and heart. Microscopic pathologic analyses of the liver reveal six major features,^{246,408,567} which occur primarily during the last “period of intoxication”: (a) eosinophilic degeneration of hepatocytes and Kupffer cells; (b) midzonal hepatocellular swelling and necrosis, with sparing of the cells in the portal area; (c) the presence of Councilman bodies coincident with hepatocyte cell death; (d) absence of leukocyte inflammatory infiltrates; (e) microvesicular fatty changes and lipid accumulation, likely secondary to decreased apolipoprotein synthesis by hepatocytes; and (f) retention of the reticulin structure. YFV antigen and RNA are demonstrable in hepatocytes by immunohistochemistry or in situ hybridization,¹⁸⁷ and this coupled with the absence of inflammation, suggests that the cell death is mediated directly by virus infection, likely via apoptotic mechanisms.^{567,666}

In the kidney, severe eosinophilic degeneration and a microvesicular fatty change of renal tubular epithelium are observed, analogous to that seen in the liver. Viral antigen can be detected by immunohistochemistry in renal tubular cells.¹⁸⁷ Glomerular damage and albuminuria with changes in the basement membrane and degeneration of cells lining Bowman's capsule may be due to direct viral injury⁵⁶⁷ or secondary to decreased blood flow during the sepsis syndrome.²⁴⁶ The spleen shows an overall loss of lymphocytes, hyperplasia of the follicle, appearance of large mononuclear tissue histiocytes, and significant degeneration of cells with accumulation of fragmented nuclei.⁴⁰⁹ In monkeys, necrosis of B-cell follicular areas of the spleen is more apparent.⁵⁶⁸ In the heart, myocardial cells also undergo apoptotic changes as in other organs, in the absence of a significant cellular inflammatory response. Patchy lesions have been described in sinoatrial (SA) node and bundle of His,⁴⁹⁵ which could explain the paradoxical bradycardia (Faget's sign) and late cardiac death, observed in some severe YFV cases.

Hemorrhagic manifestations and damage to and plasma leakage from capillaries are characteristic findings of severe

YFV infection.⁵⁶⁷ The bleeding manifestations are attributed to decreased synthesis of vitamin K–dependent coagulation factors by the injured liver, disseminated intravascular coagulation, and reduced platelet numbers and function. Beyond direct bleeding, there is additional vascular dysfunction, with pleural and peritoneal effusions, and edema of several other organs, including the brain. At present, the precise pathogenesis of the vascular leakage syndrome associated with YFV remains unknown, although highly elevated levels of proinflammatory and vasoactive cytokines are observed.⁸¹⁴

WEST NILE VIRUS

History, Global Distribution, and Epidemic Cycle

West Nile virus (WNV) was first isolated in 1937 in the West Nile district of Uganda from a woman with an undiagnosed febrile illness.⁷⁶⁶ Historically, WNV caused sporadic outbreaks of a mild febrile illness in regions of Africa, the Middle East, Asia, and Australia. Indeed, in the 1950s, detailed studies of WNV showed recurrent outbreaks in Israel^{66,260} and high levels of seroconversion in adults from Egypt^{352,549}; these outbreaks and others in Africa generally were not associated with severe human disease. However, in the 1990s, the epidemiology of infection changed. New outbreaks in Eastern Europe were associated with higher rates of neurologic disease.³⁴⁸ In 1999, WNV entered North America, and caused seven human fatalities in the New York area as well a large number of avian and equine deaths. Over the last decade, WNV has spread to all 48 of the lower United States as well as to parts of Canada, Mexico, the Caribbean, and South America. Because of the increased range, the number of human cases has continued to rise: in the United States between 1999 and 2012, 36,500 cases were confirmed and associated with 1,500 deaths (<http://www.cdc.gov/ncidod/dvbid/westnile/surv&control.htm>).

WNV cycles in nature between *Culex* mosquitoes and birds, but also infects and causes disease in humans, horses, and other vertebrate species. (Fig. 26.7) Ticks also have been implicated as having a minor role in transmission in some parts of the world,⁵¹⁰ although few isolates have been obtained. Although its enzootic cycle is overwhelmingly between mosquitoes and birds, with vertebrate species serving as “dead-end” hosts because of low-level and transient viremia, nonviremic transmission of WNV between co-feeding mosquitoes³³⁰

suggests that vertebrates could act as reservoirs for mosquito infection. Most (~85%) human infections in the Northern Hemisphere occur in the late summer, with a peak number of cases in August and September. This reflects the seasonal activity of *Culex* mosquito vectors and a requirement for virus amplification in the late spring and early summer in avian hosts. In warmer parts of the world, virtually year-round transmission has been observed. Although more than 100 avian species are susceptible to WNV infection, in the United States, some are particularly vulnerable, with a large number of deaths in crows, blue jays, and hawks. The magnitude of dying birds in a community in the early summer often predicts the severity of human or equine disease weeks later.⁴¹⁵ Ecologic studies suggest that *Culex pipiens*, the dominant enzootic (bird-to-bird) and bridge (bird-to-human) vector of WNV in urbanized areas in the northeast and north-central United States, shifts its feeding preferences from birds to humans during the late summer and early fall, coincident with the dispersal of its preferred host, the American robin (*Turdus migratorius*).³⁹³

WNV Diversity

Sequencing and phylogenetic analysis of full-length genomes has resulted in a division of WNV strains into four distinct lineages,^{67,358,447,510} with lineage 1 strains further separated into three clades (1a, 1b, and 1c). This topic has been analyzed in great detail in a recent study.⁵³⁷ Clade 1a comprises isolates from Europe, the Middle East, Russia, and the Americas, and includes all strains from the recent epoch in the United States and Canada. Clade 1b contains the naturally attenuated Australian variant, Kunjin virus, which forms a tight cluster with approximately 2% to 3% difference at the amino acid level from North American WNV strains.⁷¹⁹ Clade 1c comprises isolates from India only. Historically, lineage 2 isolates were isolated from sub-Saharan Africa and Madagascar, and generally showed less ability to cause disease in humans and animals^{54,348}; a more recent study suggests that lineage 2 isolates now circulate in parts of Eastern Europe, some of which cause severe disease.²²⁶ There are fewer sequenced strains from lineage 3 and 4 WNV, with only one lineage 3 isolate from Austria in 1997³³ and several lineage 4 isolates⁵¹⁰ from Russia between 2002 and 2006. Within a given ecological niche, possibly because of the enzootic cycle, WNV has remarkable genetic stability despite its error-prone RNA-dependent RNA polymerase; full-length sequencing analysis of North American isolates over the past decade

FIGURE 26.7. Transmission cycle of West Nile virus (WNV). WNV is maintained in nature in an enzootic transmission cycle between mosquitoes and birds. Many vertebrate species, including humans, may also be infected as “dead-end” hosts for WNV. The resulting transient low-level viremia in mammalian hosts does not support sufficient infection of the mosquito vector to continue the transmission cycle.

has revealed a rate of approximately five nucleotide and fewer than one amino acid mutation per genome per year, with little geographic subdivision.^{181,810}

Clinical Features of WNV Infection

Seroprevalence studies suggest that most (~80%) cases are subclinical, without significant symptoms. Among clinical cases, many develop a self-limiting illness that is termed WNV fever. This syndrome begins after a 2- to 14-day incubation period and is characterized by fever accompanied by myalgias, arthralgias, headache, fatigue, gastrointestinal complaints, maculopapular rash, or lymphadenopathy. This nonneuroinvasive form of WNV infection can be severe, as 38% of patients with WNV fever were hospitalized with a mean length of stay of 5.4 days.³⁵⁰ A subset of the symptomatic cases progress to the neuroinvasive forms of WNV infection, including acute flaccid paralysis, meningitis, encephalitis, and ocular manifestations^{34,742}; in many instances, a combination of these syndromes is present. Overall, about 1 in 150 WNV infections result in the most severe and potentially lethal form of the disease. During an epidemic, on a human population scale, the seroconversion rate is approximately 3%^{588,832} and the attack rate for severe disease during an epidemic is about 7 per 100,000.³⁵⁰ The risk of severe WNV infection is greatest in the elderly.^{151,603,832} At least two studies have estimated a 20-fold increased risk of neuroinvasive disease and death in those older than 50 years of age.^{350,603} Persistent movement disorders, cognitive complaints, and functional disability may occur after West Nile neuroinvasive disease. West Nile poliomyelitis-like disease may result in limb weakness and long-term morbidity. Moreover, even patients with apparently mild cases of acute disease have sustained subjective and somatic sequelae following WNV infection. Therefore, the neurologic and functional disability associated with WNV infection represents a considerable source of morbidity in patients long after their recovery from acute illness.^{740,741,742,743}

Although most human WNV infections occur after the bite of an infected *Culex* mosquito, other routes including transfusion, organ transplantation, and placental and breast milk transmission. In 2002, 23 cases of WNV infection were identified after transfusion of blood products.⁶³⁹ These cases led to the development and implementation of nucleic acid amplification tests, which have been used to identify infected pools or individual blood product samples^{115,644} and largely prevent transmission by transfusion. Nucleic acid screening of blood donors have not completely eliminated transfusion-transmitted WNV infections, as “breakthrough” infections have occurred, and were attributed to units that had levels of viremia below the sensitivity of the screening assay.¹¹⁶ In addition to transfusion-associated WNV infection, several cases by organ transplantation have been reported.^{427,428} Because of the relatively low incidence of WNV infection in organ transplantation and risk of false-positives that can occur with wide scale testing, screening is not mandated.

Pathologic Features of WNV Infection

WNV causes encephalitis in several vertebrate species including humans, horses, and birds, by virtue of its ability to infect and cause injury to neurons through direct (viral-induced) and indirect (immune response induced) mechanisms.¹²⁹ Pathologic observations in humans, however, is limited by the

small number of autopsy studies on individuals succumbing to WNV infection. Gross macroscopic examination of organs (brain, lung, kidney, and spleen) tends to be unremarkable.⁶³⁰ Microscopic examination of the brain in humans and other animals reveals histologic changes that are consistent with the clinical disease.^{221,630} This includes neuronal cell death, activation of resident microglia and infiltrating macrophages, perivascular and parenchymal accumulation of CD4⁺ and CD8⁺ lymphocytes and CD138⁺ plasma cells, and formation of microglial nodules. These lesions, which tend to be patchy in distribution, occur in the brainstem, cerebral cortex, hippocampus, thalamus, and cerebellum.⁶³⁰ In addition, overt meningitis with cellular infiltrates in the meninges can be readily apparent. In some cases, destruction of vascular structures with focal hemorrhage is present, suggestive of a vasculitis; this may be associated with local compromise of the blood-brain barrier.^{200,868} Immunohistochemical analysis confirms that WNV antigen is present in neurons from multiple regions of the brain, although other cells (e.g., astrocytes or CD11b⁺ myeloid cells) may be infected to lesser degrees.^{176,208}

In addition, WNV infection can cause a poliomyelitis-like syndrome of acute flaccid paralysis.^{257,458} Patients show markedly decreased motor responses in the paretic limbs, preserved sensory responses, and widespread asymmetric muscle denervation without evidence of demyelination or myopathy.⁴⁵⁸ Microscopically, in the spinal cord, an intense inflammatory infiltrate around large and small blood vessels is observed with large numbers of microglia in the ventral horn. Anterior horn motor neurons are targeted by WNV,^{458,754} and studies suggest that axonal transport from peripheral neurons can mediate WNV entry into the spinal cord and induce acute flaccid paralysis.⁷⁰⁵

Although most mammalian WNV infections are cleared by the adaptive immune response, persistence in the kidney has been described, albeit infrequently. Hamsters experimentally infected with WNV developed chronic renal infection and viremia for up to 8 months, despite clearance from blood and the appearance of neutralizing antibodies. Although minimal histopathology was reported, WNV antigen staining was detected in the renal epithelium, interstitial cells, and tubules.⁸¹⁶ Of interest, these persistent viruses evolved genetically and no longer caused neuroinvasive disease on challenge of naïve animals.⁸⁹⁵ Analogous to the studies in hamsters, WNV RNA was demonstrated in 5 of 25 urine samples from convalescent humans 1.6 to 6.7 years after the initial infection, although infectious virus was not successfully isolated.⁵⁹⁹ However, a separate larger study did not detect viral RNA in urine, and thus analysis of additional patient cohorts may be required to better define renal persistence and its significance in humans.²⁵⁴

Persistent WNV infection in the CNS also has been suggested by experimental infection studies in monkeys, hamsters, and mice. In monkeys, WNV persisted at least 5.5 months after initial infection and was isolated in the cerebellum and cerebral subcortical ganglia but had lost its neurovirulence and cytopathic properties.⁶⁵⁵ In hamsters, persistent WNV RNA and foci of WNV antigen-positive cells were identified in the CNS of hamsters between 28 to 86 days after infection,⁷⁵⁸ and this was associated with long-term neurologic sequelae. In mice, infectious WNV persisted in the brains of wild-type animals up to 4 months, and viral RNA could be detected at 6 months in up 12% of mice, even in animals with subclinical infection.¹⁶ Consistent with this, virus-specific B- and

T-cell immune responses persisted in the CNS of mice up to 4 months after infection.⁷⁸⁵

JAPANESE ENCEPHALITIS VIRUS

History, Global Distribution, and Epidemic Cycle

Japanese encephalitis virus (JEV) is a mosquito-transmitted flavivirus and the prototype virus of the JEV antigenic serocomplex. JEV causes severe neurologic disease, primarily in Asia, where it accounts for about 35,000 to 50,000 cases and 10,000 to 15,000 deaths annually.⁸³¹ JEV epidemics were originally described in Japan in the 1870s, and the virus was initially recovered in 1935 from the brain of an infected human in Tokyo; this isolate was established as the prototype Nakayama JEV strain.⁴⁶⁰ Although most human infections are asymptomatic or result in mild symptoms, greater than 50% of the severe clinical cases are fatal or result in devastating long-term neurologic sequelae.⁷³⁶ Moreover, as JEV-induced disease largely occurs in children living in rural areas, it is likely vastly underreported in most regions of Asia.^{736,768}

The enzootic cycle of JEV is between waterbirds (e.g., egrets and herons) and mosquitoes, with pigs also serving as an amplifying host. JEV is transmitted primarily by *Culex* mosquitoes (principally *Culex tritaeniorhynchus*) that breed in rice fields and stagnant water. Humans and other vertebrate animals are considered incidental targets and dead-end hosts, as they do not produce a viremia sufficient to infect mosquitoes. Two epidemiologic patterns are observed: in northern temperate areas JEV infections occur during the summer months, whereas as in tropical climates, year-round transmission of JEV has been described.²⁶⁷

Globally, despite the introduction of several inactivated and live-attenuated vaccines (see Vaccine section below), JEV remains the most important cause of arthropod-transmitted viral encephalitis. Disease caused by JEV is widely distributed in Asia, with outbreaks historically occurring in Japan, China, Taiwan, Korea, the Philippines, India, parts of Southeast Asia, and the far-eastern region of Russia. Although cases in China appear to be declining, possibly due to large-scale vaccination campaigns, epidemic activity in India, Nepal, and other parts of Southeast Asia appears to be escalating. More recently, JEV has been described in Pakistan, Papua New Guinea, and Australia, suggesting that its geographic range may be expanding.^{312,313}

JEV Diversity

Phylogenetic analysis suggests that JEV evolved from an ancestral flavivirus in Africa within the last few centuries.²⁶⁸ Based on sequence analysis primarily of the viral structural genes, JEV was initially classified into one single serotype with four distinct genotypes (I–IV),^{145,146,835} with as much as 12% variation at the nucleotide level. These divisions have been confirmed by full-length genome sequencing on a subset of isolates. Genotype I includes isolates from Thailand, Cambodia, Korea, China, Japan, Vietnam, Taiwan, and Australia from 1967 to the present. Genotype II includes strains from Thailand, Malaysia, Indonesia, Papua New Guinea, and Australia from 1951 to 1999. Genotype III includes isolates recovered from mostly temperate areas of Asia including Japan, China, Taiwan, the Philippines, and the Asian subcontinent between 1935 and the present. Finally, genotype IV includes strains

from Indonesia that were isolated only in 1980 and 1981. More recently, a fifth, more divergent genotype (V) has been proposed based on full-genome sequencing of a 1952 isolate from a patient in the Muar region Malaysia.⁵⁶⁰ This strain has approximately 20% and 9% nucleotide and amino acid divergence, respectively, and shows significant variation with respect to neutralization by JEV-specific monoclonal antibodies.³¹⁵

Because genotypes I and III largely occurred in epidemic regions and genotypes II and IV were associated with endemic transmission, differences in strain virulence were hypothesized to explain the epidemiologic patterns of JEV.¹⁴⁶ However, as the geographic range of JEV has expanded, there are now several examples in which strains of individual genotypes cause either epidemic or endemic disease depending on the region or country.⁷⁷²

Clinical Features of JEV Infection

In humans, the JEV infection can be asymptomatic or produce a range of clinical syndromes including a mild nonspecific febrile illness, aseptic meningitis, seizures, encephalitis, and poliomyelitis-like flaccid paralysis. Disease onset usually begins with a 1- to 2-week period of flu-like symptoms including headache, fever, cough, and upper respiratory symptoms, as well as gastrointestinal complaints such as nausea, vomiting, and diarrhea. In infants and young children the disease can progress rapidly as the virus invades the CNS and infects and injures neurons. CNS invasion is heralded by nuchal rigidity, photophobia, and altered mental status. JEV infection in the CNS can share features with Parkinson's disease including mask-like facies, hypertonia, tremor, and cogwheel rigidity. Other CNS symptoms include seizures (more common in children than adults), ataxia, involuntary movements (e.g., choreoathetosis, facial grimacing, and lip-smacking), and cranial nerve palsies. Associated with this are elevated white blood cell counts and pressure in the cerebrospinal fluid (CSF) and abnormal electroencephalography (EEG) examinations. Imaging studies in the brain have revealed thalamic and basal ganglia abnormalities during the acute phase of disease.⁷⁶⁸ Upper rather than lower extremity paralysis is more common, and lower motor neuron disease of the spinal cord can develop. Death can occur, especially in children, within 3 to 5 days of CNS symptoms, or much later due to complications associated with hospitalization or cardiopulmonary status. A recent prospective study evaluated the clinical features and long-term prognosis of 118 children with encephalitis due to JEV in Malaysia.⁶³³ Only 44% of patients had full recovery, with 8% dying during the acute phase of the illness and 31% having persistent and severe neurologic sequelae. These included chronic seizures, motor dysfunction, and neuropsychiatric symptoms such as mental retardation and psychiatric disorders.

Pathologic Features of JEV Infection

JEV infection in the brain results in neuronal degeneration, necrosis, microglial nodule formation, and perivascular and parenchymal leukocyte infiltrates as well as focal hemorrhage. Parenchymal damage in the CNS is attributed to both direct cytopathic effect of the virus in nonrenewing populations of neurons and the resultant inflammatory state induced by activated microglia and infiltrating leukocytes. Although these histologic findings can occur throughout the brain, they usually are more restricted to the gray matter in the cortex, midbrain,

and brainstem, providing anatomic correlates for the tremor and dystonias associated with CNS infection. Focal lesions are seen predominantly in the thalamus and cerebral peduncles but also are commonly observed in the substantia nigra, cerebral and cerebellar cortices, and the anterior horn of the spinal cord,⁷⁶⁸ the latter of which is associated with a poliomyelitis-like acute flaccid paralysis.⁷⁷¹ In patients who die rapidly, there may be little histologic evidence of inflammation, but instead, high levels of JEV antigen can be detected in morphologically intact neurons.³⁶²

ST. LOUIS ENCEPHALITIS VIRUS

History, Global Distribution, and Epidemic Cycle

St. Louis encephalitis virus (SLEV) is a mosquito-borne member of the JEV serocomplex capable of causing severe neurologic disease in humans. SLEV was first discovered in 1933 following a large epidemic of encephalitis in St. Louis, Missouri (1,095 cases and 225 deaths).^{185,508,675} More than 10,000 cases of severe illness and 1,000 deaths have since been attributed to SLEV infection, reflecting annual endemic transmission (~50 cases/year) punctuated by epidemic periods that occur every 5 to 15 years.⁵⁶³ At least 41 epidemics of SLEV have occurred in the United States since 1933,¹⁸⁵ the largest of these in 1975.¹⁶⁷ During this epidemic, SLEV cases were reported in 29 states and the District of Columbia; the greatest number of illnesses occurred in Ohio, Mississippi, Indiana, and Illinois. Roughly 1,500 confirmed cases were reported, resulting in 171 fatalities. The most recent large outbreak of SLEV occurred in central Florida during 1990, resulting in 222 laboratory-confirmed cases and 14 deaths.⁵⁴³

SLEV is found in much of the New World; distribution ranges from Canada to Argentina, and across North America.⁶⁷⁵ SLEV is maintained in nature in enzootic cycles between *Culex* mosquitoes and passeriform and columbiform birds. Of interest, the transmission cycle of this virus varies by region due to differences in the biology of the primary vector mosquitoes.⁶⁷⁵ In the eastern and central United States, the principal vectors of SLEV are *Culex pipiens* and *Culex quinquefasciatus* mosquitoes. *Culex tarsalis* is the primary vector for SLEV in Western states, whereas *Culex nigripalpus* transmits SLEV in Florida. The avian hosts of SLEV in these transmission cycles include house finches, house sparrows, and mourning doves. The mechanism of virus transmission and amplification in South and Central America is less clear. SLEV has been isolated from 11 different mosquito genera, many of which feed primarily on mammals.

Both WNV and SLEV are antigenically related members of the JEV serogroup that share a similar transmission cycle between *Culex* mosquitoes and birds. How the introduction of WNV in North America has impacted the epidemiology of SLEV is of significant interest. Analysis of the number of neuroinvasive cases attributed to SLEV reported to the CDC between 1999 and 2007 revealed a threefold reduction by comparison with data in the pre-WNV era.⁶⁷⁴ Interpretation of this finding is complicated by changes in the intensity of surveillance and local testing for arboviral diseases in the years after the introduction of WNV. Because major epidemics of SLEV have occurred infrequently in the past, the modest number of clinical cases may simply reflect a nadir in the natural cycle of

this virus. Alternatively, the existence of cross-reactive antibodies in WNV-immune avian reservoirs may disrupt the transmission cycle of SLEV via competition for avian hosts. Although the infection of house finches with WNV has been shown to confer protection from subsequent infection by SLEV, the reciprocal is not true. Prior exposure of finches to SLEV prevents mortality following WNV infection but not the low-level of viremia that is sufficient for transmission of WNV.²³² Similar findings were reported in a golden hamster model of infection.⁸¹⁷ The disappearance of SLEV from regions of California following introduction of WNV is consistent with the notion that competition may allow for the local displacement of the virus from historically endemic areas.⁶⁷⁶ Additional study and surveillance are required to clarify the dynamics and interactions between these two related pathogens in North America.

SLEV Diversity

Phylogenetic studies grouped SLEV isolates into seven genetic lineages (I–VII), many of which were divided further into clades of related genotypes.^{421,538} These groups correspond roughly to the geographic distribution of each lineage of SLEV.⁸³⁰ For example, lineage I include viruses isolated in the western United States, whereas lineage V contains South American strains and an isolate from Trinidad. However, the relationship between phylogenetic relatedness and geographic region is imperfect. SLEV strains vary considerably with respect to virulence in avian and mammalian hosts; these differences correlate roughly with geographic distribution.^{90,571} In addition to regional persistence, sequence analysis reveals that SLEV may be transported between regions.⁴²¹

Clinical and Pathologic Features of SLEV Infection

As is the case for both WNV and JEV, the majority of SLEV infections of humans are clinically asymptomatic. The ratio of apparent to inapparent infections has been reported to range from 1:16 to 1:425.⁵⁶³ Increasing age is a significant factor influencing susceptibility to severe illness. Symptomatic illness is noted after an incubation period of 5 to 15 days and is characterized by mild malaise, fever, headache, nausea, myalgia, sore throat, and cough.¹⁰³ Severe neurologic manifestations including encephalitis and aseptic meningitis may occur and can be fatal. Case fatality rates for SLEV range from 5% to 20%, with fatalities increasing in the elderly.⁶⁷⁵ Although most SLEV cases resolve spontaneously and without sequelae, many patients (30% to 50%) experience an extended convalescence lasting up to 3 years. This phase is characterized by headache, depression, memory loss, and weakness.^{103,675}

TICK-BORNE ENCEPHALITIS VIRUSES

History, Global Distribution, and Epidemic Cycle

Tick-borne encephalitis virus (TBEV) causes a fatal neurologic syndrome that primarily affects individuals ranging from northern China and Japan, through Russia, to parts of Northern Europe.⁵²⁵ TBEV infection was first described in 1931 after a pattern of seasonal meningoencephalitis cases in Austria was observed.⁷³² In 1939, experiments confirmed that this seasonal encephalitis in humans was caused by a virus transmission by the tick, *Ixodes persulcatus*.⁹²³ Although a highly effective

FIGURE 26.8. Life cycle of tick-borne encephalitis virus (TBEV). The transmission of tick-borne flaviviruses is connected to the life cycle of the vector due to a requirement for the tick to feed prior to transition through each of its developmental stage. Ticks are infected during this blood meal, molt, and then may infect a mammalian host. Nonviremic transmission between co-feeding ticks has also been shown to be an important mechanism of transmission and is not pictured.

formalin-inactivated vaccine has been implemented in some European countries (e.g., Austria) with marked reductions in case numbers.³²⁰ TBEV-induced morbidity and mortality continue to rise.⁷⁹⁹ Between 1990 and 2007, about 9,000 cases per year were reported in Europe and Russia⁷⁹⁹; currently, TBEV is believed to cause approximately 14,000 human cases per year, the majority of which occur in parts of Russia.²⁷⁷ This increase is thought to be due to changes in climate, population dynamics and range of permissive ticks, and shifts in land usage. Within Russia, Siberia has the highest number of TBEV cases, whereas the Czech Republic has the greatest incidence.⁵²⁵ The relative virulence of TBEV decreases with its westward spread, with the far-eastern subtype having a case-fatality rate of almost 40%.

In the enzootic cycle, TBEV is maintained between ticks and different vertebrate hosts, with humans as incidental hosts (Fig. 26.8). TBEV is transmitted primarily by the hard tick *Ixodes ricinus*, although in Eastern Europe and Russia the principal vector is *Ixodes persulcatus*. Infection is seasonal, usually occurring between March and November,³⁷¹ and coincides with seasonal peaks of feeding activity of the particular tick involved in transmission. TBEV is endemic from central Europe to Far East Asia, with cases reported in 34 countries.⁷⁹⁸ Ticks can become chronically infected after sampling viremic blood, or by transstadial or transovarial transmission. In addition, infected ticks can transmit virus to uninfected ticks during co-feeding on rodents.^{277,444} This is because the local skin environment supports TBEV replication, and migratory infected cells transport virus within the skin allowing for transmission in the absence of viremia.⁴⁴³

One exception to TBEV transmission by tick inoculation is the syndrome of biphasic milk fever, which results from oral

infection and was first identified in Russia between 1947 and 1951. During milk fever epidemics, whole families contracted TBEV infection, and this was associated with the consumption of goat milk. Goats develop subclinical TBEV infection after tick bite and become the source of infectious virus after secretion into milk. Analogously, TBEV transmission to humans has been reported after consumption of unpasteurized cow or sheep milk or dairy products.²⁷⁷ These findings are supported by experiments in mice in which TBEV infection was established after oral feeding.⁶⁵⁴

TBEV Diversity

Based on sequence similarity, three main subtypes of TBEV exist: the Far Eastern genotype 1 (previously Russian Spring and Summer encephalitis), European genotype 2 (previously Central European encephalitis), and Siberian genotype 3 (previously west-Siberian). These TBEV genotypes are closely related^{218,339} and transmitted by the ticks *Ixodes ricinus* (European subtypes) and *Ixodes persulcatus* (Asian subtypes).²⁷⁷ Within these three genotypes, there is an approximately 1.2% to 1.7% difference at the amino acid level. The Far Eastern, European, and Siberian genotypes 1, 2, and 3 differ from each other by approximately 5% to 7% at the amino acid level. In addition to these three TBEV genotypes, two additional genotypes (4 and 5) have been described based on nucleotide and amino acid differences.¹⁹³ Other viruses that are antigenically related across Europe, Asia, and North America are classified as part of the TBEV serocomplex,¹¹⁸ also termed the mammalian group of tick-borne flaviviruses. In addition to TBEV, this group includes Omsk hemorrhagic fever virus (OHFV), Louping ill virus (LIV), Langat virus (LGTV), Powassan virus (POWV), Kyasanur Forest disease virus (KFDV), Kadam

virus (KADV), Royal Farm virus (RFV), Gadgets Gully virus (GGYV), Alkhurma hemorrhagic fever virus (AHFV), and Karshi virus (KSIV). Of these viruses, TBEV, LIV, and POWV cause encephalitis in humans and animals, whereas OHFV, KFDV, and AHFV cause hemorrhagic fever.^{278,695} LGTV is a naturally occurring avirulent virus (analogous to Kunjin virus among WNV strains), and no clinical disease has been reported for KSIV, RFV, or GGYV.

Clinical Features of TBEV Infection

About one-third of patients after inoculation with an infected tick will become symptomatic,³⁷¹ with men affected twice as frequently as women, although this could reflect exposure bias. The incubation period for TBEV infection in humans varies, but for most individuals is approximately 1 to 2 weeks. A prodrome of fatigue, musculoskeletal pain, and headache lasts a few days, and is followed by an abrupt onset of fever, nausea, vomiting, and myalgias; this phase is associated with thrombocytopenia, leukopenia, and mildly elevated levels of liver enzymes in the serum. Subsequent to this, several clinical syndromes of TBEV infection develop, as reviewed previously^{277,371}:

1. *Febrile syndrome.* This illness is characterized by high fever (39°C) with no evidence of neuroinvasion. It lasts from 1 to 5 days, and upon defervescence, patients recover completely.
2. *Meningitis.* This is the most common form of clinically apparent TBEV infection occurring in approximately 50% of individuals. After the onset of fever, symptoms worsen with progressive headache, nausea, vomiting, and photophobia. All patients exhibit a CSF leukocyte pleocytosis after lumbar puncture. Fever lasts 1 to 2 weeks, with gradual recovery.
3. *Meningoencephalitis.* This form occurs in approximately 10% of cases, is more severe, and is associated with damage to the CNS. Individuals become weak, lethargic, and develop focal signs of disease including hemiparesis, hemiplegia, seizures, and autonomic instability. Up to 30% of these cases are fatal, and survivors have long-term neurologic sequelae with slow convalescence.
4. *Poliomyelitis-like disease.* This is characterized by a prodrome of limb weakness or numbness that progresses to paralysis. Paralysis occurs more frequently in the upper limbs, with the proximal segments affected more often. Recovery is slow, partial, and occurs in only one-half of patients, with the remainder showing progressive deterioration.
5. *Polyradiculitis.* This syndrome has a biphasic course with fever, headache, and myalgia followed by defervescence. Approximately one week later the second phase starts and is characterized by pain and damage in peripheral nerves, sometimes coupled with meningitis. Recovery from this form of TBEV infection is usually complete.
6. *Chronic or persistent infection.* This form has been described in Siberia and Far East Russia, although not in Europe, and is believed to associate uniquely with the Siberian subtype of TBEV. Chronic or persistent infection is characterized by a late phase (months or even years later) deterioration of the neurologic sequelae that developed during the acute illness. Alternatively, chronic TBEV infection can begin with the acute phase of disease, such that neurologic symptoms occur years after a tick bite. Clinical symptoms can include epilepsy, Parkinsonian movement and cognitive disorders,

and progressive muscle atrophy, ultimately with dementia and death ensuing. Although infectious virus has not been routinely recovered in autopsy studies, a TBEV strain was isolated from a patient who died of a progressive (2-year) form of tick-borne encephalitis 10 years after experiencing a tick bite.²⁷⁶

7. *Postencephalitic syndrome.* Both retrospective and prospective clinical trials have shown that TBEV infection is associated with a slow recovery period that has considerable long-term morbidity.^{289,370,554} This postencephalitic syndrome occurs in approximately 40% to 60% of patients, and includes memory disturbances, headache, and affective and gait disorders. The frequency of these symptoms was proportionately higher in more severe cases.

Pathologic Features of TBEV Infection

Gross pathologic analysis of the brain of humans who succumb to lethal TBEV infection shows edema and hyperemia. Microscopic lesions occur in a patchy distribution throughout the CNS but are most prominent in the brainstem, basal ganglia, thalamus, cerebellum, and spinal cord. The cerebral and spinal meninges show a diffuse leukocyte infiltration, predominantly with lymphocytes. In the parenchyma of the brain and spinal cord, perivascular infiltrates, microglial nodules, and necrosis of neurons is observed. Notably, Purkinje cell neurons in the cerebellum and anterior horn motor neurons in the spinal cord are preferentially targeted and injured by TBEV.³⁷¹ Immunohistochemical analysis of brains from 28 autopsy cases²⁵⁰ showed prominent TBEV antigen staining in Purkinje cells, neurons of the dentate gyrus, the brainstem, and basal ganglia, with T lymphocytes detected in direct apposition to TBEV-infected neurons.

PATHOGENESIS AND IMMUNITY

Virus Entry and Tropism

Flavivirus entry into cells is mediated by the envelope proteins and can be considered in three relatively discrete steps (Fig. 26.9). The first step involves the attachment of the virus particle to the cell. Collisions between virions and target cells are not always productive. “Attachment factors” promote infection by increasing the duration of contact between the virion and cell surface, and thereby increase the likelihood that subsequent steps in the virus entry pathway will occur. Attachment factors are not strictly required for infection. In contrast, interactions with viral “receptors” promote required events during virus entry. Although the distinction between these two types of cellular factors is clear for some viruses (e.g., HIV), the cell biology of flavivirus entry remains poorly understood.

Several cellular factors have been suggested to function as attachment factors or receptors during the flavivirus entry (reviewed by Lindenbach, Murray, Thiel, and Rice in Chapter 25 of this volume). The interaction between flaviviruses and glycosaminoglycans (GAGs) have been documented.^{147,332,455,523} The binding site for these sulfated polysaccharides on the virion has been mapped to positively charged surfaces of the E protein.^{147,523} Passage of virus in cell culture selects for variants that bind more efficiently to GAGs, although this adaptation appears to be associated with reduced fitness *in vivo*.^{454,456,523} Treatment

FIGURE 26.9. The replication cycle of flaviviruses. Flaviviruses bind cells of the host through poorly defined interactions with one or more molecules on target cells. Viruses are internalized via clathrin-mediated endocytosis and fuse with membranes of the late endosome in a pH-dependent manner. Viral RNA replication begins shortly thereafter in association with membranes of the host cell. Cells actively replicating flaviviruses reveal striking host membrane rearrangements thought to coordinate the processes of genomic RNA replication and virus assembly. Virus particles assemble at and bud into the endoplasmic reticulum and are secreted from the cell. During egress, virion maturation occurs in the acidic compartments of the Golgi and is characterized by cleavage of the prM protein by a furin-like protease.

of cells with heparan sulfate can inhibit infection.^{147,457,485} GAGs are thought to promote more efficient attachment to cells via electrostatic interactions with the virus particle.

Cellular lectins also increase the efficiency of flavivirus attachment. CD209 Dendritic Cell-Specific Intercellular Adhesion Molecule-3-Grabbing Non-integrin (DC-SIGN) is a calcium-dependent c-type lectin that serves as an attachment factor for several classes of viruses (reviewed in⁸³⁹), including some flaviviruses.^{183,605,811} These interactions are mediated by N-linked sugars on the prM and E proteins of the virion.^{182,406,480,504} CD209 is expressed *in vivo* on a subset of

dendritic cells (DCs) and macrophages.⁸³⁹ The infectivity of DCs by DENV correlates with CD209 expression; immature DCs express CD209 and are more permissive to infection than mature DCs expressing lower levels of CD209.^{811,893} Antibodies against CD209 or soluble forms of this lectin are capable of blocking DENV infection of DCs.^{605,811} Experiments with truncated forms of CD209 suggest that internalization of CD209 is not required to increase the efficiency of virus attachment to selected cell types.⁵⁰³ CD209L Dendritic Cell-Specific Intercellular Adhesion Molecule-3-Grabbing Non-integrin-Related protein (DC-SIGNR)^{183,811} and the mannose

receptor (MR)⁵⁵⁶ have also been identified as attachment factors for flaviviruses.

Recent studies have identified members of the TIM and TAM families of phosphatidylserine receptors that function as attachment and potentially signaling factors for flaviviruses. These cellular proteins directly (in the case of TIM1) or indirectly (in the case of TAM proteins) bind lipids incorporated into the membrane of the virus particle. The expression pattern of this family of molecules may explain, in part, the broad cellular tropism of these viruses *in vitro*. Furthermore, the interaction of cellular proteins with the lipid envelope of the virion, thought to be buried by the dense icosahedral array of E proteins described above), raises questions about the structure(s) of infectious flaviviruses.^{543a}

Flavivirus enter cells via clathrin-mediated endocytosis.^{2,152,262,424,838} Elegant single-particle tracking studies of DENV suggest that virions move across the surface of cells until they encounter preformed clathrin-coated pits. Virus particles are then internalized and traffic into late Rab7-positive endosomal compartments where viral fusion occurs.⁸³⁸ Fusion between viral and cellular membranes is triggered by the acidic environment of endosomes. How viruses sense the low-pH environment is not completely understood, but may involve the protonation of key histidine residues on the E protein.^{241,375,608} Fusion may also be governed by the lipid composition of the endosome.⁹⁰⁹ That flaviviruses have the ability to fuse with synthetic liposomes devoid of proteins indicates that this process does not require interactions with a cellular receptor.^{162,264}

The molecular basis for the tropism of flaviviruses is unknown. A wide variety of cell lines representing different lineages and species may be infected *in vitro*. This suggests cellular factors involved in virus entry are either highly conserved (from mosquitoes to man) or redundant. Targets for flavivirus infection *in vivo* appear more restricted and include monocytes, macrophages, hepatocytes, neurons, endothelial cells, and DCs.^{38,704} Tropism may be regulated at a postentry level through the activities of interferon and interferon-stimulated genes.^{704,859}

Mechanisms of Dissemination

Blood-Borne Viruses

For both viscerotropic (e.g., DENV and YFV) and encephalitic (e.g., WNV, JEV, and TBEV) flaviviruses, the skin is the likely initial infection site after insect inoculation, with resident dendritic cells^{117,529} or epidermal keratinocytes⁴⁷⁸ believed to be the primary target cells. The dose of virus inoculated by the mosquito under conditions of natural infection is not known precisely, but likely ranges from 10^3 to 10^5 plaque-forming units (PFU),^{731,791} depending on the flavivirus and insect vector. Active WNV replication can be detected at the subcutaneous site of infection within one day of infection,¹⁰⁷ and virus spread to the lymph node occurs in animals infected by mosquitoes or with mosquito salivary extracts.^{731,792} Proteins in mosquito saliva alter cytokine levels and other components of innate immunity, leading to local immunosuppression or dysregulation,⁷²⁹ and enhanced spread and replication.

Flaviviruses disseminate to local lymph nodes either associated with migratory infected dendritic cells⁶⁶³ or as free virus that transudates directly into lymphatic fluid.³⁶⁹ Macrophages on the floor of the subcapsular sinus and in the medulla of lymph nodes capture viral particles efficiently, serving as possible targets of virus amplification infection and initiators of innate and adaptive immune responses.³⁶⁹ Virus produced in the draining

lymph nodes likely spreads to intravascular venous compartments via efferent lymphatic drainage. Virus in the bloodstream can directly infect blood cells or visceral tissues, which can result in further dissemination and secondary viremia.

The infectivity of flaviviruses in plasma, the fluid component of blood, appears remarkably short, with a half-life in mice ranging from 2 to 10 minutes for DENV and WNV, respectively.²⁴² The loss of infectivity is due in part, to complement (C3 and C4 components) opsonization via mannose-binding lectin recognition of N-linked glycans on the surface of virions.²⁴² The short half-life of infectious flavivirus in plasma may also reflect sequestration and removal by different visceral organs.³⁵⁵ Alternatively, flaviviruses may transit rapidly into the cellular compartment of blood. One study of patients with DENV infections of different disease severity showed DENV antigen (prM and NS3) predominantly in cells of monocyte (CD14⁺, CD32⁺) lineage, with up to 80% to 90% of cells of expressing viral antigen.²¹⁶ This finding of DENV in blood monocytes is consistent with prior literature⁵²⁶ but contrasts with newer studies in rhesus macaques, suggesting that platelets become positive for dengue antigen during the course of infection.⁶³² Finally, another explanation for the rapid drop of plasma infectivity is that flaviviruses adhere readily to erythrocytes in whole blood.⁶⁸³

Neurotropic Viruses

Flavivirus neuropathogenesis requires neuroinvasiveness, the capacity to enter the CNS, and neurovirulence, the ability to propagate efficiently within cells of the CNS. In classical studies, phenotypic distinctions were made among different arthropod-borne viruses on the basis of replication efficiency and pathogenic potential in peripheral versus CNS tissues.⁵ A main principle was the relationship between peripheral virus burden and the propensity to cause neuroinvasion. Viruses with a low capacity to replicate in the periphery generally had less neuroinvasive potential, regardless of their intrinsic neurovirulence. Aerosol-acquired and, perhaps, mucosal infections are possible exceptions, as these may use alternate routes of CNS entry.

Data from several studies indicate that the time of onset, magnitude, and duration of viremia, as well as the integrity of the host immune system influences the risk of entry into the CNS. Therefore, the neuropathogenic potential of most flaviviruses is a balance between the replication efficiency and the effectiveness of early host defenses in clearing viremia. Neuroinvasiveness is affected by both viral and host factors. Based on genetic analysis of virulent and attenuated strains of JEV, TBEV, YFV, and WNV, viral determinants of neuroinvasiveness map primarily to the E protein.^{54,56,130,541,615,616} The mechanisms associated with these genetic determinants have not been determined, but are believed to relate to increased viral infectivity of key target cells through enhanced binding and penetration.

Animal models of infection of encephalitic flaviviruses have begun to define factors that govern virus entry into the brain and spinal cord. Crossing of the blood-brain barrier (BBB) likely occurs through a hematogenous route, as increased viral burden in the serum correlates with earlier and enhanced viral entry into the brain.²⁰⁴ Accordingly, changes in endothelial cell permeability may facilitate CNS entry; these may be triggered by vasoactive cytokines^{509,868} or activation of matrix metalloproteinases that degrade the BBB extracellular matrix.^{845,864} Additional possible mechanisms may contribute to CNS infection of flaviviruses, including the following: (a)

direct infection or passive transport through the endothelium,^{212,488,846} and (b) infection of olfactory neurons and rostral spread from the olfactory bulb.¹⁰⁷ Access through the olfactory bulb is believed to occur either after infection by the aerosol or intranasal route^{602,618,669} or in the context of hematogenous dissemination of virus.⁵⁴² The olfactory bulb is vulnerable to direct infection because of the exposure of its nerve terminals within the olfactory mucosa; (c) a “Trojan horse” mechanism in which virus is transported by infected immune cells that traffic to the CNS⁸⁶⁵; (d) access to the CNS after breakdown of BBB integrity^{139,412}; and (e) direct axonal retrograde transport from infected peripheral neurons.^{351,584,705,860} Although much has been learned from infection studies in mice and hamsters, the precise mechanisms of CNS entry of encephalitic flaviviruses in humans and other animals requires additional study.

Mechanisms of Immune Control: Innate Immunity

Cellular Innate Immunity

MACROPHAGES

Although only limited studies have directly addressed the function of cellular innate immunity in flavivirus infection, emerging data suggest that macrophages play key roles in orchestrating control of infection. Macrophages can limit infection through direct viral clearance, enhanced antigen presentation to B and T cells, and production of proinflammatory or antiviral cytokines and chemokines.^{426,527} The protective role of macrophages is highlighted by studies in mice, which demonstrated exacerbated WNV, TBEV, DENV, or YFV disease after selective macrophage depletion.^{63,234,390,663,924} Macrophages may control flaviviruses through the production of nitric oxide (NO) and other reactive oxygen intermediates after stimulation of inducible nitric oxide synthetase (NOS-2).^{422,484,712,713} Activation of macrophages in response to flavivirus infection also promotes release of type I interferon (IFN), tumor necrosis factor (TNF)- α , interleukin (IL)-1 β , IL-8, and other cytokines, some of which have antiviral activity and reduce viral replication, at least in culture.⁷⁵⁷ Despite their protective role in innate defense, macrophages also are targets of infection by some flaviviruses,^{416,441,684} and have the potential to contribute to pathogenesis through antibody-dependent enhancement of infection mediated by Fc- γ and complement receptors.^{123,261,641} The macrophage cell surface receptor CLEC5a independently has been reported to interact with DENV directly, resulting in DAP12 phosphorylation and the release of proinflammatory cytokines.¹⁴⁴ Therefore, in some circumstances macrophages can contribute to flavivirus-induced disease, although the contribution to clearance versus pathogenesis may vary depending on the specific virus, the presence of preexisting nonneutralizing antibodies, and the specific proinflammatory molecules that are produced.

NEUTROPHILS

Although polymorphonuclear leukocytes (neutrophils) are among the first circulating leukocytes to respond to infection or inflammatory stimuli, their function in flavivirus infection remains uncertain. Some studies suggest a protective function; however, others indicate that neutrophils can contribute to flavivirus pathogenesis. A protective role was reported in the context of WNV infection as macrophages produced neutrophil chemoattractive chemokines (CXCL1 and CXCL2),

neutrophils rapidly migrated to the site of infection, and mice depleted of neutrophils 1 or 2 days after virus infection developed higher viremia and experienced earlier death.³⁰ Paradoxically, if neutrophils were depleted prior to infection, viremia was reduced and survival was enhanced.³⁰ Analogously, depletion of neutrophils resulted in prolonged survival and decreased mortality in Murray Valley encephalitis virus-infected mice, and neutrophil infiltration and disease correlated with NOS-2 expression within the CNS.¹⁴ Finally, transcriptional gene signatures from whole blood showed a greater abundance of neutrophil transcripts in patients who progressed to DSS, a finding supported by higher plasma levels of proteins associated with neutrophil degranulation.³³⁴ Although further studies are warranted, neutrophils may prevent or promote flavivirus disease, depending on the specific virus and immunologic context.

DENDRITIC CELLS

Human peripheral blood contains two types of dendritic cells (DCs), plasmacytoid DCs (pDCs) and myeloid DCs (mDCs), which can be distinguished based on function and distinctive surface markers. pDCs lack phagocytic capacity and are less efficient in capturing and presenting antigens to T cells, but they produce extraordinarily high levels of type I IFN in the presence of viruses or bacteria,⁷⁵⁹ and are thus considered to play a crucial role in antiviral immunity.^{802,803} Low levels of DENV replication were observed in pDCs, but proinflammatory cytokines were produced rapidly and could accumulate to high levels. This cytokine response was not dependent on viral replication, but dependent on endosomal toll-like receptor 7 (TLR7), and could be induced by purified DENV RNA.^{797,862} In prospective clinical studies, the absolute number of circulating pDCs remained stable early in moderately ill children with dengue fever or other nondengue, febrile illnesses. However, there was an early decrease in circulating pDCs in children who subsequently developed DHF, as a blunted blood pDC response was associated with an altered innate immune response, higher viremia levels, and severe disease.⁶⁴⁶ Of interest, the host origin of the flavivirus influences the response that is generated by pDCs, as WNV grown in mammalian cells was a potent inducer of IFN- α secretion in pDCs, whereas pDCs failed to produce IFN- α when exposed to WNV grown in mosquito cells.⁷⁶²

mDCs reside and circulate throughout the body, enabling them to transport antigens from the periphery to lymphoid tissues. They are professional antigen-presenting cells that transmit incoming infectious signals to B and T cells to orchestrate rapid and efficient adaptive immune responses.⁷⁸³ mDCs are more readily infected by flaviviruses *ex vivo*, and are thought to contribute to viral spread and early immune system priming depending on the particular virus. For example, WNV efficiently infects mouse mDCs and induces a type I IFN and proinflammatory cytokine response through RIG-I-like pattern recognition receptors and IPS-1-dependent signaling cascade.^{178,800} In comparison, also in mice, JEV induced impaired responses through MyD88-dependent and -independent pathways, with blunted co-stimulatory molecule expression and production of the antiinflammatory cytokine IL-10, which resulted in poor T-cell priming.⁷ DENV productively infects human mDCs and induces release of high levels of chemokines and proinflammatory cytokines, with the notable exception of type I IFN,^{686,687} although this latter finding has not been observed with all strains of DENV.^{35,469} Moreover, mature mDCs were capable of

supporting antibody-dependent enhancement (ADE) of DENV, whereas immature DCs, due to expression of higher levels of DC-SIGN, did not promote ADE.⁸⁷

Despite an accumulating wealth of data on purified mDC *ex vivo*, few studies have assessed their direct function *in vivo* in the context of flavivirus infection. A recent report showed that selective genetic deletion of CD8 α ⁺ mDCs resulted in defective cross-presentation and virus-specific CD8⁺ T-cell responses to WNV.³³¹ The generation of diphtheria toxin receptor transgenic mice that selectively deplete DC subsets may allow further dissection of the net function of mDCs in flavivirus infection.

NATURAL KILLER CELLS

Natural killer (NK) cells are innate immune lymphocytes that serve as a first line of defense against a variety of infections.⁷⁵ NK cells mediate protection through the recognition and killing of target cells and the production of immunomodulatory cytokines, particularly IFN- γ , which enhances innate immunity and shapes the subsequent adaptive immune response.¹⁶¹ Unlike adaptive T and B lymphocytes, NK cells do not rearrange their receptor genes somatically, but rely on a fixed number of inhibitory and activating cell receptors that recognize major histocompatibility complex (MHC) class I and class I-like molecules, as well as other ligands.¹¹¹ The function of NK cells in flavivirus infection remains uncertain. Some *in vitro* studies suggest that human NK cells can expand and inhibit WNV infection of cells through both cytolytic (antibody-dependent cell-mediated cytotoxicity [ADCC]) and non-cytolytic (IFN- γ) activities.⁹¹⁴ The activating human NK-cell receptor, NKp44 has been reported to directly bind to domain III of DENV and WNV E proteins. This interaction induced IFN- γ secretion and lysis of WNV-infected targets by NK cells.³²⁸ However, flavivirus infection may inhibit NK-cell killing by increasing the cell surface expression of class I MHC molecules,^{209,329,400} which sends a negative signal to NK cells.³⁶³ *In vivo*, the function of NK cells in flavivirus infection also remains unclear. Although NK cells expand and become activated in YFV- and DENV-infected humans and mice,^{140,610,747} antibody depletion of NK cells in mice did not alter morbidity or mortality after WNV infection.⁷⁵⁵

$\gamma\delta$ T CELLS

$\gamma\delta$ T cells contribute to the innate defense against several viruses by virtue of their relative frequency in blood and epithelial sites and ability to respond rapidly to nonpeptide antigens and secrete proinflammatory cytokines and chemokines. Because they lack classical MHC restriction, $\gamma\delta$ T cells can react with viral antigens in the absence of conventional antigen processing.⁷⁸¹ $\gamma\delta$ T cells are divided into functionally distinct subsets, which have disparate effects on host immunity to pathogen infection. Splenic V γ 1⁺ $\gamma\delta$ T cells contribute to eliminating *Listeria* infection by virtue of their IFN- γ activity.⁵³⁶ In comparison, V γ 4⁺ $\gamma\delta$ T cells enhance Th1-cell activation through IFN- γ - and CD1-dependent mechanisms.³⁴⁹ To date, much of the initial analysis of $\gamma\delta$ T cell function during flavivirus infection has focused on studies with WNV in mice, although recent studies confirm that human and monkey $\gamma\delta$ T cells also are activated rapidly after YFV infection.^{196,611} Mice deficient in $\gamma\delta$ T cells were more susceptible to WNV infection,⁸⁶⁷ and this was in part due to their ability to produce IFN- γ , which has direct antiviral effects.⁷⁵⁶ Moreover, mice depleted of V γ 1⁺

$\gamma\delta$ T cells have enhanced viremia and higher WNV mortality, whereas the opposite is observed with depletion of V γ 4⁺ $\gamma\delta$ T cells.⁸⁷⁷ Subsequent work showed that $\gamma\delta$ T cells also contribute to the development of a protective CD8⁺ T-cell response against WNV, as TCR δ ^{-/-} mice were more susceptible than wild type mice to secondary WNV challenge.⁸⁶⁶ This priming effect may reflect DC maturation (increased expression of surface co-stimulatory and class II MHC molecules and secretion of IL-12) that is promoted by $\gamma\delta$ T cells after activation by WNV.²³¹

MAST CELLS

Mast cells contribute to a variety of inflammatory reactions and host defense against pathogens⁵¹⁹ by secreting chemokines, cytokines, and inflammatory lipid mediators and granule-associated products. Mast cells express several Fc receptors, reside primarily in tissues, and associate closely with vascular beds.⁷⁴⁴ Recent studies suggest that infection or activation of mast cells in tissues by DENV can promote viral clearance⁷⁷⁶ or have immunopathologic consequences that contribute to the vasculopathy associated with secondary infection. DENV infection of mast cells *ex vivo* resulted in increased secretion of chemokines, including CCL5 without inducing degranulation,³⁹⁸ and production of vasoactive cytokines was enhanced in the presence of subneutralizing concentrations of antibody that promotes ADE.³⁹⁹ Antibody-enhanced DENV infection of mast cells in culture also resulted in significant production of TNF- α , which can stimulate endothelial cells,¹⁰⁸ as well as massive mast cell apoptosis that occurs via global caspase activation.¹⁰⁹ Although more investigation is needed, DENV-infected mast cells may contribute to endothelial cell activation and permeability via local production of cytokines.

Cell-Intrinsic Immunity

RECOGNITION AND CONTROL OF FLAVIVIRUSES BY HOST SENSORS

Interferon (IFN) responses are an essential host defense program against many viruses, including flaviviruses. IFNs are produced during the earliest stages of viral infection after recognition of pathogen-associated molecular patterns (PAMPs) by specific pathogen recognition receptors (PRRs). In mammalian cells, the host detects and responds to infection by flaviviruses by primarily recognizing viral RNA through several distinct PRRs including the cell surface and endosomal RNA sensors TLR3 and TLR7, and the cytoplasmic RNA sensors retinoic acid-inducible gene I (RIG-I) and melanoma-differentiation-associated gene 5 (MDA5) (Fig. 26.10). Binding of single- and/or double-stranded (ds) viral RNA to these PRR results in downstream activation of transcription factors, such as IFN regulatory factors 3 and 7 (IRF-3 and IRF-7) and NF- κ B, and induction of IFN- α and IFN- β . Secretion of IFNs followed by engagement of the IFN- $\alpha\beta$ receptor (IFNAR) in an autocrine and paracrine fashion activates janus kinase (JAK)-signal transducer and activator of transcription (STAT) pathway-dependent and independent signal transduction cascades⁴⁶⁵ that induce the expression of hundreds of IFN-stimulated genes (ISGs), a subset of which likely have antiviral activity against flaviviruses (Fig. 26.11).⁷³³

Recent studies suggest that RIG-I and MDA5 contribute to the induction of host IFN and antiviral response to flaviviruses (Fig. 26.10). Murine embryonic fibroblasts (MEFs) deficient in RIG-I and MDA5 showed decreased IRF-3 activation, delayed induction of host interferon and ISG responses, and augmented WNV and DENV replication.^{239,240,500,604} RIG-I

FIGURE 26.10. Detection of flavivirus RNA by pathogen recognition receptors (PRRs) and mechanisms of viral evasion.

(Left) Cytoplasmic PRR and signaling cascade. Infection by flaviviruses produces double-stranded RNA (dsRNA) replication intermediates that display motifs recognized by retinoic acid-inducible protein I (RIG-I) and possibly, the melanoma disassociation-associated 5 (MDA5) helicase. Binding of viral RNA promotes an interaction with IPS-1 that results in recruitment of signaling proteins (NEMO and TRAF3) that activate interferon regulatory factor 3 (IRF-3) and nuclear factor kappa B (NF- κ B). These transcription factors translocate to the nucleus and bind to the promoter region of the IFN- β gene leading to transcription and translation. (Right) Toll-like receptor (TLR) signaling cascade. In some cells, the transmembrane PRRs TLR3 and TLR7/8 in endosomes recognize double-stranded RNA (dsRNA) and single-stranded RNA (ssRNA) motifs leading to recruitment of cytoplasmic adaptor molecules (TIR-domain-containing adapter-inducing interferon- β [TRIF] and Mmeloid differentiation primary response gene (88) [MYD88]), respectively), which initiate signaling cascades (via I kappaB kinase [IKK] TANK-binding kinase 1 [TBK1] Receptor-Interacting Protein 1 [RIP-1] and interleukin-1 receptor-associated kinase 4 [IRAK-4]) that activate IRF-3, IRF-7, and NF- κ B, resulting in IFN- β gene transcription. Mechanisms of evasion by flaviviruses are believed to include the following: (1) a delay in recognition of West Nile virus (WNV) RNA by RIG-I; (2) impairment of RIP-1 signaling by high mannose carbohydrates on the structural E protein; (3) attenuation of TLR3 signaling by the NS1 protein; (4) reduction in IFN- β gene transcription by the Kunjin virus (KUNV) NS2A protein; (5) reduction of type I IFN production by catalytically active dengue virus (DENV) NS2B-NS3 protein; and (6) viral dsRNA intermediates localized to specialized membrane vesicles, which prevent rapid detection by intracellular sensors such as RIG-I.

appears to prime the early type I IFN response, whereas MDA5 has a more apparent role in a second phase of IFN-dependent gene expression that occurs later in the course of infection. A genetic deficiency of IPS-1 (also known as Cardif, mitochondrial antiviral signaling protein [MAVS], or virus-induced signaling adaptor [VISA]), an essential RIG-I and MDA5 adaptor molecule that is anchored to the outer leaflet of mitochondria, completely disabled the innate IFN response^{178,240} and was asso-

ciated with enhanced WNV lethality in mice with dysregulated immune responses.⁸⁰⁰ RIG-I-dependent signaling appears dominant in mice, as animals deficient in RIG-I were more vulnerable to JEV infection,³⁷⁹ and a deficiency of proteins that regulate the Tripartite motif-containing protein 25 (TRIM25)-mediated ubiquitination and activation of RIG-I resulted in enhanced WNV replication and mortality.⁸⁶³ Consistent with this, JEV and DENV induce the host type I IFN response

FIGURE 26.11. Type I interferon (IFN) signaling and mechanisms of disruption by flaviviruses. Secretion of IFN by a flavivirus-infected cell results in autocrine and paracrine signaling through the heterodimeric IFN- $\alpha\beta$ receptor (IFNAR). Binding by IFN results in activation and tyrosine phosphorylation of Janus kinase (JAK) family members (JAK1 and Tyk2) and the cytoplasmic tail of the IFNAR. This promotes recruitment of the signal transducers and activators of transcription (STAT1) and STAT2, which themselves become phosphorylated by the JAKs. Phosphorylated STAT1 and STAT2 proteins heterodimerize, associate with IRF-9, and translocate to the nucleus, where they bind interferon-sensitive response element (ISRE) sequences to induce expression of hundreds of interferon-stimulated genes (ISGs). Mechanisms of evasion by flaviviruses are believed to include the following: blockade of phosphorylation of (1) Tyk2 and (2) JAK1 by flavivirus NS5; (3) activation of a phosphotyrosine phosphatase by JEV NS5; (4) reduction in STAT2 gene and protein expression by Dengue virus (DENV) and Yellow fever virus (YFV) NS5; (5) attenuation of STAT signaling by flavivirus NS4B; (6) downregulation of the IFNAR through virus-induced redistribution of cellular cholesterol; and (7) antagonism of interferon-induced protein with tetratricopeptide repeats (IFIT) family genes effector functions by 2' O methylation of flavivirus RNA.

through a mechanism involving RIG-I/IRF-3 and NF- κ B.¹³⁶ MDA5 may be less important for flavivirus recognition, as IFN production by MDA5^{-/-} myeloid dendritic cells remains largely intact after WNV infection,²⁵⁶ and a deficiency of MDA5 in mice did not affect survival after JEV,³⁷⁹ although higher mortality rates are observed after WNV infection (H. Lazear and M. Diamond, unpublished results). Despite data from murine embryonic fibroblasts (MEF) suggesting that RIG-I and likely MDA5 recognize WNV RNA and induce type I IFN responses, IFN- α and β production in mice appears independent of IPS-1⁸⁰⁰ or the downstream transcription factor IRF-3.^{89,174} Therefore, individual cell types (myeloid, fibroblast, and neuronal) use distinct PRR responses to protect

against flavivirus infection through both IFN-dependent and IFN-independent pathways.¹⁷⁷

TLR3, which is expressed on the surface of fibroblasts and in the endosomes of myeloid cells, promotes IRF-3 phosphorylation after binding ds viral RNA through a complex signaling cascade that includes recruitment of TIR-domain-containing adapter-inducing interferon- β (TRIF) and activation of the kinases TANK-binding kinase 1 (TBK1) and I kappaB kinase (IKK ϵ).^{535,735} Initial studies with TRIF-deficient MEF suggested that TLR3 may be dispensable for recognition of flaviviruses in cells,²³⁹ although subsequent cell culture studies showed a proinflammatory and protective effect of TLR3 after DENV infection.^{604,834} Experiments in TLR3^{-/-} mice have had

conflicting results. TLR3^{-/-} mice injected by an intraperitoneal route paradoxically showed decreased WNV lethality despite higher peripheral viral titers, presumably because of blunted cytokine responses (e.g., TNF- α) that normally facilitate virus entry into the CNS.⁸⁶⁸ Consistent with a possible pathologic role, preliminary studies suggest a functional TLR3 allele is a risk factor for severe human TBEV infection.³⁹⁷ In comparison, other studies with TLR3^{-/-} mice and a different North American WNV strain showed increased viral burden in the brain and enhanced lethality,¹⁷⁶ as might be anticipated for a PRR that triggers a protective host immune response. *Ex vivo* and *in vivo* experiments suggest a cell-specific role for TLR3, as it protected against WNV largely by restricting replication in neurons.

TLR7 is an endosomal PRR that detects guanosine and uridine-rich single-stranded RNA²⁰⁷ and activates IRF-7 via the Myeloid differentiation primary response gene (88) (MYD88) adaptor molecule. IRF-7 was identified as a primary regulator of antiviral gene induction after YFV infection,²⁴⁷ with some of this activation occurring through TLR7 recognition of viral RNA.^{667,668,797,862} Similarly, DENV stimulates IFN production in pDCs in a TLR7-dependent manner after virus uncoating.⁸⁶² The antiviral IFN- α response against WNV is mediated primarily by IRF-7,¹⁷⁵ and at least some of this signal is attributed to recognition of viral RNA by TLR7. Indeed, both TLR7^{-/-} and MyD88^{-/-} mice show increased susceptibility to WNV infection, and this was associated with increased local infection and decreased production of IL-1 β , IL-6, IL-12, IL-23, and several chemokines, which altered leukocyte trafficking and virus control in several tissues.^{572a,805,828,878} In addition to its possible antiviral effects as an IFN effector molecule (see below), dsRNA-dependent protein kinase R (PKR) also may serve as a PRR for inducing interferon responses. In three different human cell lines, small interfering RNA (siRNA) knockdown and chemical inhibition of PKR blocked WNV-induced IFN synthesis.²⁵⁵

TYPE I IFN SIGNALING PATHWAY

Type I IFNs induce an antiviral state by upregulating genes with both direct and indirect inhibitory functions.⁶⁵¹ In mice, for example, there are at least 14 IFN- α and one IFN- β isoforms, in addition to multiple other subtypes.⁸⁴⁰ IFN- α and IFN- β are considered the dominant functional type I IFN in humans and are secreted by many cell types following virus infection. Type I IFN primes adaptive immune responses through stimulation of DCs, activation of B and T cells, and by preventing death of recently activated T cells.^{451,452,784} Pretreatment of cells with IFN- α or IFN- β inhibits flavivirus replication *in vitro*,^{68,203,482,505,849} but treatment after infection is less effective.^{13,166,203,704,778} Although flaviviruses can antagonize IFN-induced responses after infection, IFN still restricts replication and spread *in vivo*. Mice lacking the type I IFN receptor (IFNAR^{-/-}) or downstream signaling components (e.g., STAT1) show enhanced lethality and replication after infection with WNV,^{385,704} DENV,⁷⁴⁸ YFV,⁵⁴⁸ or MVEV.⁴⁹⁶ Increased infection occurred in normally resistant cell populations and tissues after flavivirus infection of IFNAR^{-/-} mice, suggesting that IFN acts, in part, to restrict viral tropism. The importance of type I IFN in controlling flavivirus infection has been confirmed in therapeutic disease models. Pretreatment of animals with IFN- α or inducers of IFN- α attenuates infection by SLEV, WNV, YFV, and Modoc viruses.^{106,366,463,464,650,812} The relevance of these pathways has been confirmed *in vivo* as

several recent microarray analyses have shown that animals or primary cells infected with flaviviruses produce a potent innate antiviral transcriptional gene signature characterized by genes downstream of type I IFN signaling.^{35,334,668,710}

TYPE I IFN-INDUCED GENES THAT CONTROL FLAVIVIRUS INFECTION

Progress has been made in defining the specific IFN-induced antiviral genes that limit flavivirus infection (Fig. 26.11). Initial studies showed that dsRNA-dependent PKR and 2'-5'-oligoadenylate synthase (Oas) proteins mediated intrinsic cell resistance to WNV.⁷⁰⁶ PKR is activated by binding dsRNA and phosphorylates the eukaryotic translation initiation factor 2 (eIF2- α) resulting in attenuation of protein synthesis.⁵⁵² PKR also may have independent antiviral effects by activating signaling pathways that augment type I IFN production^{48,255} and directly regulating IFN- β mRNA stability.⁷³⁸ RNase L is activated by 2'-5'-linked oligoadenylates that are synthesized by Oas enzymes. RNase L inhibits viral infections by functioning as an endoribonuclease that cleaves viral RNA^{920,921} and by generating small self-RNA PAMPs that amplify antiviral immunity through a RIG-I and MDA5-dependent pathway.^{517,518} RNase L^{-/-} MEF and macrophages supported increased WNV replication *in vitro*,^{706,717} and knockdown of RNase L enhanced infectivity in human cells.⁴⁸³ Moreover, mice deficient in RNase L showed increased lethality following WNV infection, with higher viral loads in peripheral tissues at early time points after infection.⁷⁰⁶

Although susceptibility to flaviviruses in mice has been mapped to a mutation in the *Oas* gene 1b, resulting in the expression of a truncated Oas isoform,^{532,643} the mechanism of control by this gene appears independent of RNase L⁷¹⁷ and the type I IFN signaling pathway.¹⁰⁴ Knock-in of the wild-type Oas1b allele into a flavivirus-induced disease susceptible mouse generated a resistant phenotype,⁷¹⁶ and murine cells that ectopically expressed Oas1b resisted WNV infection by preventing viral RNA accumulation inside infected cells.³⁷² Although biochemical studies have shown that Oas1b itself is an inactive 2'-5' Oas, recent experiments suggest that Oas1b inhibits Oas1a activity, resulting in reduced 2'-5' oligoA production in response to poly(I:C).²²⁰ Negative regulation of 2'-5' Oas by inactive Oas1b proteins may tune the RNase L response that could cause significant damage in cells, if it were not tightly controlled.

More recent studies have used ectopic expression and siRNA or short hairpin RNA (shRNA) knockdown strategies to identify key and novel ISGs that restrict infection of different flaviviruses. A large-scale ectopic lentivirus screen identified several regulatory and effector ISGs that inhibit infection of WNV and YFV in human cells.⁷³³ Ectopic expression of ISG15, a ubiquitin-like protein that conjugates to key proteins of the cellular innate immune response,²⁵³ inhibited replication of the JEV in human medulloblastoma cells,³⁴³ although ISG15^{-/-} mice or neurons are not more susceptible to WNV infection (M. Samuel, D. Lenschow, and M. Diamond, unpublished observations). Members of the Interferon-inducible transmembrane (IFITM) proteins were recently shown to inhibit an early entry step in infection of DENV and WNV in cells.⁹⁴ This observation was confirmed by ectopic expression studies in HEK293 cells.³⁵⁹ Other studies have suggested that viperin^{359,804} and ISG20^{359,922} also may inhibit infection by flaviviruses. Although the field is rapidly advancing with respect to identifying antiviral ISG against

flaviviruses, definitive studies in genetically deficient animals may be required to establish the cell- and tissue-specific nonredundant effects of individual ISG in controlling flavivirus infection in the context of a robust type I IFN response.

Chemokines

Depending on the specific flavivirus infection, individual chemokines and cytokines can either protect or contribute to pathogenesis. For encephalitic flaviviruses, production of inflammatory chemokines in the brain by neuronal and non-neuronal cells coordinates recruitment of lymphocytes for clearance of viral infection. Chemokines that have been detected in the brain or CSF after WNV, JEV, or TBEV infection of mice include CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC), CCL2 (MCP-1), CCL3 (MIP-1a), CCL4 (MIP-1b), and CCL5 (RANTES).^{245,291,404,746,825} WNV infection in the brain is associated with the early expression of the T-cell chemoattractant CXCL10 by virally infected neurons;⁴⁰⁴ this expression proceeds in a caudal to rostral direction with higher levels detected in the cerebellum. This regional heterogeneity in CXCL10 expression is due to differential regulation by WNV-infected cortical versus cerebellar granule cell neurons and leads to enhanced trafficking of WNV-specific T cells that express the CXCL10 receptor CXCR3 into the cerebellum.⁹¹³ Loss of CXCL10 or CXCR3 via targeted deletion or neutralizing antibody administration leads to decreased recruitment of WNV-specific CD8⁺ T cells into the CNS, especially within the cerebellum, increased viral loads, and enhanced mortality.^{404,913} In contrast, antagonism of polarized CXCR4–CXCL12 interactions along the BBB improved survival from lethal WNV infection through enhanced intraparenchymal migration of WNV-specific CD8⁺ T cells within the brain, leading to reduced viral loads and decreased immunopathology.⁵⁴⁰

A genetic deficiency in CCR2, a chemokine receptor on inflammatory monocytes and other leukocyte subtypes, resulted in markedly increased WNV-induced mortality in C57BL/6 mice,⁴⁷⁷ and was associated with a selective reduction of monocyte accumulation in the brain. Subsequent experiments showed that CCR2 mediates selective peripheral blood monocytoysis in the context of WNV infection, and this is critical for accumulation of protective monocytes in the brain. Although a protective role for CCL2–CCR2 interactions was observed with a virulent WNV isolate, an opposing phenotype was seen after infection with an attenuated strain; neutralization of CCL2 reduced the number of microglia in the brain during WNV infection but prolonged the life of infected animals.²⁵² Therefore, depending on the virulence of the strain, CCL2–CCR2-dependent monocyte accumulation and migration may differentially affect disease outcome after WNV infection.

Additional studies have established that the chemokines CCL3, CCL4, and CCL5, all of which bind to the chemokine receptor CCR5, are strongly induced within the brain after WNV infection.^{258,404,746} Moreover, targeted deletion of CCR5 is associated with depressed leukocyte trafficking, increased viral burden, and enhanced mortality.²⁵⁸ An analysis of WNV infection in humans with CCR5Δ32, a defective CCR5 allele, showed that homozygosity for the allele correlated with an increased risk of symptomatic disease.^{259,475,476} Because the mouse studies examined the entire brain with regard to expression and leukocyte trafficking, and the human studies did not report on specific neurologic symptoms, it remains

unclear whether CCR5-expressing leukocytes also exhibit regional specificity during CNS recruitment. Finally, a case of YFV vaccine-associated viscerotropic disease was associated with genetic polymorphisms in both CCR5 and CCL5 genes.⁶⁶²

For viscerotropic flaviviruses such as DENV, the function of chemokine interaction with their receptors remains less certain. Although DENV-infected wild-type mice produce high levels of chemokines CCL2, CCL3, and CCL5 in their spleen and liver, CCR1^{−/−} mice had a phenotype similar to wild-type mice, whereas infection of CCR2^{−/−} or CCR4^{−/−} mice showed attenuated lethality, liver damage, leukocyte activation, and levels of IL-6 and IFN-γ without significant differences in viral load.²⁸³ Therefore, chemokine–chemokine receptor interactions in the context of DENV infection appear to contribute to the development of disease. Nevertheless, in an encephalitic mouse model of DENV infection, CXCL10 interaction with CXCR3 was required for clearance and resistance to infection.³⁴⁴

Complement Activation and Flaviviruses

The complement system is a family of serum and cell surface proteins that recognize PAMPs, altered-self ligands, and immune complexes. Although complement activation inhibits infection of many viruses (reviewed in^{27,788}), it has both protective and pathogenic roles in flavivirus infection depending on the specific virus, phase of the infection, and immune status of the host. Activation of the complement cascade triggers several antiviral functions, including pathogen opsonization and/or lysis, and priming of adaptive immune responses. Complement is activated through the classical, lectin, and alternative pathways depending on specific recognition molecules.^{855,856} Classical pathway activity is triggered by C1q binding to antigen–antibody complexes on the surface of pathogens. The lectin pathway is initiated by mannose binding lectin (MBL) or ficolin recognition of carbohydrate structures on the surface of microbes or apoptotic cells. The alternative pathway is constitutively active at low levels through the spontaneous hydrolysis of C3 and also amplifies activation of the classical and lectin pathways. The classical, lectin, and alternative pathways generate convertase enzymes (C4bC2a for classical and lectin, and C3bBb for the alternative), which cleave C3, the central component of the complement system, and expose a reactive internal thioester bond on C3b necessary for covalent attachment to target surfaces. The binding of C3b back to C4b2a and C3bBb C3 convertases forms the classical and alternative pathway C5 convertases, respectively. These enzymes cleave C5 and promote assembly of C5b-9 membrane attack complex (MAC), which lyses pathogens or infected cells. Sublytic amounts of C5b-9 on a cell surface can activate granulocytes and endothelial cells, whereas soluble C5b-9 independently induces inflammation through cytokine induction. The release of anaphylatoxins (C3a and C5a) by the C3 and C5 convertases also promotes chemotaxis of immune cells via the interaction with specific G-protein coupled transmembrane receptors (C3aR and C5aR). Deposition of C3 and C4 fragments (C3b and C4b) on a pathogen facilitates binding and phagocytosis by complement receptors (CR1, CR3, CR4, and CRIg), a process called opsonization, which helps to clear microbial infections.¹²⁵

PROTECTIVE ACTIVITY OF COMPLEMENT ON FLAVIVIRUS INFECTION

Complement can limit flavivirus infection by stimulating adaptive immune responses or by directly neutralizing infection. In support of an immune priming role for complement, C3^{−/−} mice are more

susceptible to lethal WNV infection and show greater viral burden and reduced antiviral antibody titers.⁵⁴⁷ Infection studies with mice lacking C1q, MBL, C4, or factor B establish that all complement activation pathways protect against WNV infection.^{243,545} However, each activation pathway appears to exert distinct effects in response to WNV infection. Humoral IgM responses to WNV depend upon activation of C3 by the lectin recognition pathway. In contrast, both the lectin and alternative pathways appear necessary for efficient T-cell priming, as C4^{-/-}, factor B^{-/-}, and factor D^{-/-} mice exhibited reduced WNV-specific CD8⁺ T-cell responses.⁵⁴⁵ The T-cell defects in C4^{-/-} mice may be indirect as depressed IgM responses could affect viral opsonization and antigen presentation. The terminal lytic complement components (C5–C9) do not appear to serve a major function in protection, as C5 neither contributed to protection against WNV pathogenesis nor augmented the neutralizing efficacy of complement-fixing anti-WNV neutralizing antibodies in mice.⁵⁴⁶

Flaviviruses directly trigger complement activation, which can inhibit infectivity. Increasing concentrations of serum complement neutralize WNV or DENV in cell culture and *in vivo* in the absence of antibody, and this depends on recognition of N-linked glycans on the surface of the virion by MBL.²⁴² Complement activation by flaviviruses occurs *in vivo*, as C3 and C4 consumption occur prior to the induction of a specific antibody response.⁵⁴⁵

Complement augments antibody-mediated neutralization of flaviviruses, including YFV, DENV, and WNV.^{192,547,775} The C1q component of complement is sufficient to enhance the potency of antibody neutralization as it reduces the number of antibodies that must bind the virion to neutralize infectivity.⁵⁴⁶ The protective efficacy of flavivirus neutralizing antibodies *in vivo* correlates with IgG subclasses that efficiently fix complement.^{546,724}

PATHOLOGIC EFFECTS OF COMPLEMENT ON FLAVIVIRUS INFECTION

In myeloid cells that express complement receptors, antibody-dependent complement activation paradoxically may enhance viral infection.^{123,124} Blockade of complement receptor-3 (CD11b/CD18) abrogated the complement-dependent enhancement of WNV infection in this model system. Therefore, under certain circumstances, antibody and complement-dependent opsonization of flaviviruses may increase infection in myeloid cells.

During severe secondary DENV infection, a vascular leakage syndrome occurs with fluid transudation into serosal spaces. Although the pathogenesis of DENV infection remains incompletely understood, a pathologic role for complement activation has been proposed.^{28,85} In early clinical studies, reduced levels of C3 and C4 and factor B and increased catabolic rates of C3 and C1q were observed, particularly in patients with severe DENV disease.⁸⁵ In addition, C3 breakdown products and anaphylatoxins accumulated in the circulation of severely ill patients and peaked at the day of maximum vascular leakage.^{157,516} Circulating immune complexes formed by virions and DENV-specific antibodies have been hypothesized to cause the pathologic complement activation.⁸⁵ One alternative hypothesis is that infected cells express sufficient amounts of DENV antigens (E or NS1 proteins) on their surface, thereby facilitating immune complex formation and complement deposition.⁶⁹ Indeed, DENV-infected endothelial cells activate human complement in the presence of antibodies resulting in C5b-9 deposition.^{26,28}

Humoral Immunity

Humoral immunity contributes significantly to the host response to flavivirus infection. Virus challenge experiments using inbred strains of mice identified the importance of B cells during a protective response.^{204,205} The importance of antiviral antibody has been established directly. Passive administration of virus-reactive mAbs, purified polyclonal γ -globulin, and immune sera confers significant protection in small animal models of flavivirus infection.²⁰² For example, transfer of heat-inactivated WNV-immune serum into wild-type mice completely protects from lethal infection with WNV; administration of antibody into *uMT* or *RAG1* KO mouse strains prior to virus challenge delays mortality but does not protect from death.²⁰⁴ Antibodies may also protect from disease when administered therapeutically after infection.²⁰² Although neutralizing antibody titers correlate with protection by several flavivirus vaccines,^{60,320,533,575} the relationship may be imperfect.⁸¹ Antibodies also may exert protective effects via effector functions mediated by the Fc portion of the antibody molecule, including complement fixation, antibody-mediated cellular cytotoxicity, and facilitating virus and clearance.^{546,724,725} Protective antibodies that bind epitopes on the prM and E structural proteins incorporated into virions, as well as the nonstructural protein NS1, have been characterized.^{211,381}

STOICHIOMETRIC REQUIREMENTS FOR NEUTRALIZATION

Antibody-mediated neutralization of flaviviruses requires engagement by antibodies with a stoichiometry that exceeds a particular threshold (reviewed by²¹¹). From this perspective, the number of antibodies bound to the virion is controlled by the functional avidity of the antibody for viral antigens on the virion, and the number of times an epitope is displayed on the virion in a context in which it is accessible for antibody binding. Complexities that modulate the accessibility of viral epitopes include the dense arrangement of E proteins on the surface of the mature virion,^{497,624,629,787} the extent of virion maturation,⁶⁰⁷ and the structural dynamics of the virus particle.^{210,497} Antibody avidity determines the fraction of accessible antibody epitopes bound by antibody molecules at any concentration of antibody.^{211,403} The mAb E16 binds a relatively accessible epitope on the E-DIII-LR and supports neutralization at a low occupancy.⁶⁴⁸ Similar findings were reported for neutralizing anti-DENV antibodies that bind a similar epitope.²⁷⁹ By comparison, antibodies that bind poorly accessible “cryptic” epitopes may neutralize only at saturation.^{280,607,648,787} It is notable that some epitopes are not displayed with a frequency that allows engagement of the virion with a stoichiometry that allows for neutralization, even when fully occupied. Therefore, antibodies that bind cryptic epitopes may be incapable of neutralization regardless of their functional affinity for the virion.^{607,648} The limited neutralizing activity of prM-specific antibodies may simply reflect an inability to bind the virion enough times (Fig. 26.12).

The stoichiometric requirements for neutralization of WNV have been estimated.⁶⁴⁸ Experiments with E-DIII-LR-specific mAbs demonstrate that neutralization requires occupancy of 20% to 25% of accessible epitopes on the mature virion. Because only 120 epitopes on the mature virion are accessible for antibody binding, this translates into a requirement for engagement of the virion by roughly 30 antibody molecules. The functional significance of this number is not yet clear. Of potential interest, it does agree with predictions of the “coating

FIGURE 26.12. Antibody affinity and epitope accessibility govern the neutralization potency of anti-flavivirus antibodies.

Neutralization of flaviviruses is a multiple-hit phenomenon that requires engagement of the virion by antibody with a stoichiometry that exceeds a threshold estimated at approximately 30 antibody molecules. The number of antibody molecules bound to the virion at any given antibody concentration is determined in part by the strength of the antibody–virion interaction and epitope accessibility. **A:** The affinity of antibody–virion interactions determines the fraction of epitopes displayed on the virion bound by antibody at given concentration. **(Right)** Therefore, changes in antibody affinity (conferred in this example via mutation of the antibody epitope) results in a change in the number of antibodies bound to the virus particle at each antibody dilution and a shift in the neutralization profile toward higher concentrations of antibody. **B:** Epitope accessibility, which may vary considerably depending on its location on the virion and the maturation state of the virion, governs the occupancy requirements for neutralization. For a theoretical flavivirus displaying 180 epitopes, an epitope occupancy of 17% is required to exceed a stoichiometric threshold of 30 antibody molecules. A reduction in epitope accessibility translates into increases in the fraction of epitopes that must be engaged to support virus neutralization. **(Right)** Antibodies that bind highly accessible determinants may completely neutralize infection at relatively modest occupancy (60%, *green shading*), whereas antibodies that bind poorly accessible structures neutralize infection only at full occupancy (*red shading*). (Reproduced from Dowd KA, Pierson TC. Antibody-mediated neutralization of flaviviruses: a reductionist view. *Virology*. 2011;411(2):306–315, with permission.)

theory” model that suggest the number of antibodies required to neutralize a virion is determined by surface area of the virus particle.¹¹⁴ It will be important to determine the stoichiometric requirements for neutralization by antibodies that bind other epitopes; this is complicated experimentally as antibody-mediated neutralization of many other epitopes is modulated by the extent of maturation and structural dynamics of the virion.

MECHANISMS OF NEUTRALIZATION

Antibodies have the capacity to neutralize directly the infectivity of viruses via several mechanisms that act at distinct steps in the virus life cycle. Anti-flavivirus antibodies can block virus attachment to host cells.^{170,317,624} At present, it is unknown whether

antibodies that block attachment to cells do so by interfering with specific interactions with receptor on the target cells or via a general steric hindrance mechanism. Flavivirus-reactive antibodies also may block infection to virions after the attachment step. Studies by Gollins and Porterfield demonstrated that antibodies could block the uncoating and infectivity of WNV, even when added after virions attached to cells. Furthermore, they demonstrated that antibodies could directly block fusion of virions to synthetic liposomes.²⁶³ These observations have been expanded to include other flaviviruses and antibodies.^{689,822} Analysis of the ability of a large panel of TBEV-reactive antibodies to block liposomal fusion reveal mAbs capable of blocking fusion completely (25% of antibodies tested), partially (58% of

antibodies tested), or not at all (17% of antibodies tested).⁷⁸⁶ These results suggest that an ability to block fusion is a relatively common functional property of neutralizing antibodies. Two recent atomic structures illustrate different ways antibodies that decorate the virus particle may block fusion. Experiments with Fab fragments of mAb E16 suggest this antibody blocks the radial expansion of the virus particle and traps it in an intermediate step of the fusion process following exposure of the virus to acidic conditions.³⁸² In contrast, the complex epitope recognized by the mAb CR4354, which was composed of multiple E proteins, suggests a mechanism of inhibition by which E proteins on the surface are cross-linked together, preventing the rearrangements that propel fusion.³⁸⁴

How an antibody neutralizes flavivirus infection may depend on context, as an individual antibody may block virus infection at more than one step of the virus entry pathway. For example, mAb E16 partially blocks attachment at relatively high antibody concentration. Virus binding is not significantly inhibited at lower concentrations of antibody at which significant virus neutralization is observed.^{210,624} This observation suggests that the stoichiometric requirements for neutralization may differ depending on the mechanism of inhibition.

ANTIBODY-DEPENDENT ENHANCEMENT OF INFECTION

Antibody-dependent enhancement (ADE) of infection describes a phenomenon in which a significant increase in the efficiency of virus infection is observed in the presence of virus-reactive antibody.^{306,307} Although ADE has been demonstrated for several families of viruses *in vitro*, a role for enhancing antibodies *in vivo* has been suggested in only a few contexts, including secondary DENV infection.³⁰⁰ Passive transfer of DENV-reactive antibodies increases viral burden and exacerbates disease in an IFN- $\alpha\beta\gamma$ receptor-deficient murine model (AG129 mice) of infection and pathogenesis^{39,912} and increases viremia in primates.^{265,297} The mechanism of ADE has been studied extensively, but remains incompletely understood. ADE is most commonly, although not exclusively, observed on cells that express Fc- γ or complement receptors.³⁰⁰ Antibodies enhance infection by increasing the efficiency of virus attachment to target cells and thus, is of significantly reduced magnitude on cells with the capacity to bind viruses via other attachment factors.⁶⁴⁸ For example, Fc- γ -receptor expressing immature dendritic cells do not support ADE due to the expression of CD209. By comparison, ADE occurs with mature dendritic cells that lack expression of CD209.⁸¹¹ ADE can be inhibited by antibodies that block Fc- γ -receptor interactions,⁶⁴⁰ enzymatic removal of the heavy chain of the antibody molecule,⁹¹² and removal of the N-linked sugar on IgG molecules.^{39,265,648}

What are the properties of antibodies that enhance infection? Virus neutralization and the phenomenon of ADE are related by the number of antibody molecules bound to the virion; antibodies that neutralize flaviviruses also have the potential to enhance infection at subneutralizing concentrations.²¹¹ Antibodies that bind the virion with low affinity will enhance infection at higher concentrations relative to molecules that engage the virion via high affinity interactions. Furthermore, antibodies that recognize poorly accessible epitopes support ADE at higher concentrations than antibodies that bind readily accessible determinants. Estimates of the stoichiometric requirements for ADE identified a requirement for more than a single antibody molecule; enhancement of Fc- γ -RII-expressing cells

required engagement of at least 15 DIII-LR-specific mAbs.⁶⁴⁸ Presumably this is the minimal number of antibodies required for stable attachment of the virion-antibody complex to cells. Whether the requirements for ADE differ on cells expressing other Fc- γ -receptor molecules has not been investigated.

Recent studies indicate that complement can restrict ADE. Complement minimized ADE of WNV and DENV infection in Fc- γ R-expressing cells.^{544,899} Experiments with mouse sera deficient in individual complement components indicate that C1q is sufficient to restrict ADE of WNV infection *in vitro*. This effect was IgG subclass-dependent, as C1q restricted ADE by a human IgG₃ isotype-switch variant, but had little effect on IgG₂ and IgG₄ subclass variants; these results correlate with the known affinity of human IgG subclasses for C1q.⁷⁴ The addition of complement reduces the stoichiometry of neutralization by antibodies such that for IgG subclasses that bind C1q avidly, the reduced threshold of neutralization falls below the minimal number of antibodies required for ADE of infection.^{647,648}

THE REPERTOIRE OF ANTIBODIES ELICITED *IN VIVO*

The composition of the polyclonal antibody response elicited by infection is incompletely understood. Recent studies suggest that the humoral immune response of humans is directed against the highly conserved fusion loop of E-DII.^{61,191,823} In agreement, biochemical studies with recombinant proteins and virus particles incorporating mutations in the fusion loop suggest a significant portion of the reactivity maps to this conserved structure.^{168,169,628} Functional approaches to measure the relative contribution of epitopes on the E protein toward the neutralizing and protective activity of sera are being developed.^{186,607,628,853}

T-Cell-Mediated Control

CD8⁺ T CELLS

CD8⁺ T cells, by virtue of their ability to lyse infected target cells and produce inflammatory cytokines (e.g., IFN- γ and TNF- α), can have either protective or pathologic effects depending on the context. Indeed, depending on the flavivirus strain and experimental system, beneficial or adverse functions of CD8⁺ T cells have been reported. Experiments in small animal models and *in vitro* demonstrate that T lymphocytes can be an essential component of protection against infection by several different flaviviruses, including WNV, DENV, YFV, and JEV.^{77,100,101-102,490,595,596,664,752,765,901,903} Consistent with this, individuals with hematologic malignancies and impaired T-cell function have an increased risk of neuroinvasive WNV infection.^{598,658} Upon recognition of a flavivirus-infected cell that expresses class I MHC molecules, antigen-restricted cytotoxic T lymphocytes (CTLs) proliferate, release proinflammatory cytokines,^{101,209,388,426,664} and lyse cells directly through the delivery of perforin and granzymes A and B, or via Fas-Fas ligand interactions. After WNV infection, mice deficient in CD8⁺ T cells had higher and sustained WNV burdens in the spleen and CNS and increased mortality.^{752,870} CD8⁺ T cells require perforin and Fas ligand interactions to control infection of virulent North American WNV strains, as mice deficient in these molecules had increased CNS viral burdens and lethality.^{753,755} Moreover, adoptive transfer of wild-type but not perforin or Fas-ligand-deficient CD8⁺ T cells decreased CNS viral burden and enhanced survival. In comparison, granzymes appear important for the control of the lineage II isolate Sarafend, with perforin, Fas, and Fas ligand having a

more limited role in modulating infection.⁸⁷¹ The net function of CD8⁺ T cells in infection by other encephalitic flaviviruses (e.g., JEV or MVEV) also varies. Initial reports showed that JEV-specific cytotoxic CD8⁺ T cells could reduce production of infectious virus from infected macrophage and neuronal-like cells *in vitro*.⁵⁹⁵ Moreover, adoptive transfer of anti-JEV CD8⁺ T cells by an intracerebral route protected adult but not newborn or suckling BALB/c mice against lethal JEV challenge.⁵⁹⁶ However, in vaccine immunization studies, challenge experiments in CD8 T cell^{-/-} mice, indicate that CD8⁺ T cells are dispensable and that antibody was the most critical component of protection.⁶³⁷ CD8⁺ T cells may have a lesser role *in vivo* in JEV infection because of active subversion of the antigen-presentation pathway by the virus; recent reports suggest that JEV infection leads to active depletion and impairment of CD8 α ⁺CD11c⁺ dendritic cells,^{7,8} which are the cells that predominantly mediate cross-presentation of antigen and priming of CD8⁺ T-cell responses *in vivo*.³³¹ With MVEV infection, effector CD8⁺ T cells in the brain appear pathologic, as mice deficient in granule exocytosis (perforin or granzyme B) or Fas-mediated cytotoxicity showed delayed and reduced mortality.⁴⁷¹

For DENV, which generally does not cause encephalitis, the protective or pathologic function of CD8⁺ T cells depends on whether the response is primary or memory. During primary infection of mice, depletion of CD8⁺ T cells before infection resulted in significantly higher viral loads. DENV-specific CD8⁺ T cells produced IFN- γ and TNF- α , and exhibited cytotoxic activity *in vivo*.⁹⁰³ In comparison, a pathogenic role of CD8⁺ T cells has been described during secondary DENV infection. Due to the significant amino acid sequence homology among the four serotypes, there is a high potential for T-cell cross-reactivity during secondary heterologous DENV infection. Serotype cross-reactive CD8⁺ T cells are preferentially activated during secondary infection in humans in a phenomenon termed “original antigenic sin”.⁵⁷⁷ These cross-reactive CD8⁺ T cells exhibit altered cytokine production and reduced cytolytic activity.^{49,57,524,578} Aberrant cytokine production by T cells could contribute to severe DENV disease, as higher levels of proinflammatory mediators may contribute to endothelial cell dysfunction or damage, leading to plasma leakage.⁵³⁴

CD4⁺ T CELLS

CD4⁺ T cells can restrict or contribute to pathogenesis depending on the flavivirus, and whether the response is primary or anamnestic. Studies in mice have shown that CD4⁺ T cells restrict pathogenesis of primary WNV infection. A genetic or acquired deficiency of CD4⁺ T-cell function resulted in protracted WNV infection in the CNS that culminated in uniform lethality by 50 days after infection. CD4⁺ T cells protect against primary WNV infection by providing help for antibody responses, sustaining WNV-specific CD8⁺ T-cell responses in the CNS that enable viral clearance, producing antiviral cytokines, and killing cells.^{102,765} A protective role for CD4⁺ T cells against lethal JEV infection in mice was observed as depletion reduced and adoptive transfer promoted survival.⁷⁷ Moreover, in humans, impaired JEV-specific CD4⁺ T-cell function (e.g., IFN- γ secretion) was seen preferentially in patients with encephalitis and neurologic sequelae.⁴³⁰ Consistent with this, CD4^{-/-} mice also showed greater susceptibility to CNS infection by a neuroadapted strain of YFV.⁴⁹⁰ In comparison,

depletion of CD4⁺ T cells prior to DENV infection in mice had no effect on tissue viral burden, DENV-specific antibody titers or neutralizing activity, or CD8⁺ T-cell responses.⁹⁰¹

Memory CD4⁺ T cells can have protective or pathologic consequences, depending on the context. For DENV, immunization schemes that elicit antigen-specific CD4⁺ T cells prior to infection of mice resulted in significantly lower viral burden after challenge with homologous DENV.⁹⁰¹ Therefore, induction of CD4⁺ T cells by immunization can contribute to viral clearance. However, during heterologous secondary DENV infection, cross-reactive CD4⁺ memory T cells may be stimulated by antigen from the secondary infection. These CD4⁺ T cells then augment the response of memory CD8⁺ T cells, which can result in an overexuberant production of inflammatory cytokines and an increased risk for severe DENV disease.⁵⁷

CD4⁺CD25⁺FoxP3⁺ REGULATORY T CELLS

Regulatory CD4⁺ T cells (Tregs) are a subset of CD4⁺ T cells that can suppress effector T cells to control reactivity to self-antigens and pathogens.^{702,801} These cells function to blunt inflammation and to maintain antigen-specific T-cell homeostasis.^{432,625} A recent study showed that Tregs control the development of symptomatic WNV infection in humans and mice.⁴⁴⁹ Symptomatic WNV-infected mice and humans had lower Treg frequencies compared with asymptomatic cohorts, and Treg-deficient mice developed lethal WNV infection at a higher rate than controls. Of interest, in severe DENV infection in humans, although Tregs expand and function normally, their relative frequencies are insufficient to control the immunopathology of severe disease.⁵⁰⁶ Given their relatively recent identification, future studies will undoubtedly clarify the role of Tregs in preventing or promoting flavivirus pathogenesis.

FLAVIVIRUS IMMUNE EVASION

Evasion of the Type I IFN Pathway. Flaviviruses have evolved several strategies to avoid and/or attenuate induction of type I IFN and its effector responses. In cell culture, flaviviruses are largely resistant to the antiviral effects of IFN once infection is established.²⁰³ This may explain in part, the relatively modest therapeutic window for IFN- α administration that has been observed clinically in animal models or humans infected with JEV, SLEV, and WNV.^{132,374,670,770} Experiments by several groups have demonstrated that individual flaviviruses attenuate IFN signaling at distinct steps in the cascade.

Inhibition of IFN- β Gene Induction. Three mechanisms have been described by which flaviviruses minimize the induction of IFN- β (Fig. 12.10).

1. IFN- β gene transcription. Studies with KUNV have identified the nonstructural protein NS2A as an inhibitor of IFN- β gene transcription.^{491,492} Incorporation of an A30P mutation of NS2A into a KUNV genome resulted in a virus that elicits more rapid and sustained synthesis of type I IFN; infection of this mutant virus *in vitro* and *in vivo* was highly attenuated. The exact cellular target of NS2A and its mechanism of inhibition remain unknown.
2. PRR detection. Highly pathogenic WNV strains evade IRF-3-dependent recognition pathways without actively antagonizing the host defense signaling pathways.²³⁹ Virulent WNV strains delay activation of PRR, such as RIG-I,

through mechanisms that are not clear to provide the virus with a kinetic advantage in the infected cell to elude host detection during replication at early times after infection.³⁸⁶ In contrast, less pathogenic strains of WNV induce greater levels of IFN at early time points.³⁸⁵

3. PRR signaling. Studies in human mDCs suggest that DENV infection interferes with the type I IFN production⁷⁹⁷ prior to *IFN-β* gene induction as IRF-3 phosphorylation is not induced.^{686,687} Although the precise mechanism remains uncertain, ectopic expression studies show that a catalytically active NS2B–NS3 complex is sufficient for IFN antagonism. Activation of IRF-3 in response to dsRNA (poly (I:C)) also was inhibited in HeLa cells infected with WNV or stably propagating a subgenomic replicon.⁷³⁴ Although initial experiments suggested that NS1 might mediate this inhibitory effect,⁸⁸⁶ more recent work has questioned these results.⁴² Alternatively, the high mannose carbohydrates on the E protein may independently block the production of *IFN-β*, IL-6, and TNF- α that is induced by dsRNA in macrophages. This effect was not directly dependent on TLR3 but instead occurred downstream at the level of the signaling intermediate and NF- κ B activator, receptor-interacting protein (RIP)-1.¹⁷ Based on studies with macrophages from different age cohorts, this E protein-dependent inhibitory pathway may be dysregulated in elderly humans, leading to a pathogenic cytokine response.⁴¹⁶ Although the mechanistic basis for how specific forms of the E protein alter antiviral signaling programs remains uncertain, glycosylated E proteins can potentially signal through multiple cell surface lectins including the mannose receptor⁵⁵⁶ and CLEC5a.¹⁴⁴

Impaired IFNAR Pathway Signaling. In addition to antagonizing induction of *IFN-β* gene responses, several flaviviruses target the JAK-STAT signaling pathway for evasion to prevent the induction of antiviral ISG with possible antiviral activity (Fig 26.11). Therefore, even when type I IFN is produced, it may not achieve its inhibitory effect because of attenuated signaling capacity. Because the nonstructural proteins NS2A, NS3, NS4A, NS4B, and NS5 mediate many of the viral evasion mechanisms described below, these countermeasures are largely intrinsic to infected cells.

1. Phosphorylation of JAKs. Studies with LGV and WNV have shown interference with phosphorylation of both JAK1 and Tyk2.^{68,290} A variation on this was observed with JEV, which showed complete inhibition of phosphorylation of Tyk2 with little effect on JAK1 phosphorylation.⁴⁸² Expression of a subgenomic replicon or infection of cells with DENV also inhibited Tyk2 phosphorylation and had no effect on IFNAR expression.³³³ However, there may be cell- or virus-specific effects as JEV also inhibits STAT1 and STAT2 activation in the setting of normal levels of Tyk2 phosphorylation.⁴⁷⁹
2. STAT2 gene expression. DENV antagonizes IFN function by reducing STAT2 expression.³⁶⁴ Cell lines that stably propagated subgenomic DENV replicons were resistant to the antiviral effects of IFN- α , had reduced levels of STAT2, and blunted ISG responses. DENV NS5 protein mediates binding and degradation of human but not mouse STAT2 via a ubiquitin and proteasome-dependent process,²⁰ and this species-specific effect in part explains the restriction of DENV infection in wild-type mice.²¹

3. Cholesterol redistribution. Flavivirus infection can actively promote re-localization of cholesterol to intracellular membranous sites of replication. This redistribution diminishes the formation of cholesterol-rich lipid rafts in the plasma membrane and attenuates the IFN antiviral signaling response.⁵¹²
4. NS proteins as specific IFN antagonists. Several groups have begun to define the viral determinants and mechanisms that mediate IFN attenuation. Ectopic expression studies in A549 cells with DENV showed that NS2A, NS4A, or NS4B enhanced replication of an IFN-sensitive virus by blocking nuclear localization of STAT1.⁵⁹⁴ Subsequent experiments showed that NS4B of DENV, WNV, and YFV partially block STAT1 activation and ISG induction.⁵⁹³ Mutagenesis studies have identified a sequence determinant on WNV NS4B (E22/K24) that controls IFN resistance in cells that express subgenomic replicons.²²⁷

Although NS5 attenuates JAK-STAT signaling after LGV, JEV, and TBEV infection, the mechanism of NS5 inhibition appears to have virus-specific characteristics. For TBEV, a sequence in the methyltransferase domain of NS5 binds the PDZ protein scribble to inhibit JAK-STAT signaling.⁸⁷⁹ For JEV, the N-terminal 83 residues of NS5 inhibit JAK-STAT signaling through a protein-tyrosine phosphatase-dependent mechanism.⁴⁸¹ Finally, for LGV, the JAK-STAT inhibitory domain was mapped to sites within the RNA-dependent RNA polymerase domain.⁶³⁸

Impaired IFN Effector Functions. Although flaviviruses devote a significant segment of their genome to inhibiting JAK-STAT signaling, they also target individual downstream antiviral effector molecules. Viperin is a candidate antiviral ISG with inhibitory activity against HCV, influenza virus, HIV, and Sindbis virus, possibly because of its ability to alter lipid raft formation. JEV, however, counteracts viperin by promoting rapid proteasome-dependent degradation.¹³¹ The mechanism of this inhibition remains unclear, as transfection of individual JEV proteins failed to explain the phenotype, suggesting that a combined effect of viral proteins or replication is required.

More recent studies have shown that 2'O methylation modification of flavivirus RNA encoded by the methyltransferase activity of NS5 can antagonize the antiviral effects of the IFN-induced genes, IFIT-1 and IFIT-2.¹⁷⁹ A WNV mutant in NS5 (E218A) that specifically lost 2'O methylation activity replicated poorly in primary macrophages and mice, but showed restored virulence in cells and animals lacking IFN α BR or IFIT-1.

Evasion of the Complement Pathway by NS1. To minimize recognition and/or destruction by complement, viruses have evolved strategies to evade or exploit complement to establish infection.^{27,788} Flavivirus NS1 is expressed on cell surfaces, secreted from infected cells, and accumulates in the serum of infected individuals, with high circulating levels correlating with severe DENV disease.^{28,468} WNV NS1 attenuates complement activation of the alternative pathway by enhancing the cofactor activity of factor H for factor I-mediated cleavage of C3b to iC3b, which decreases deposition of C3b and the C5b–C9 membrane attack complex on cell surfaces.¹⁵⁴ As an additional mechanism by which flaviviruses can evade complement, NS1 also binds to C4 and C1s, which enhanced the cleavage of C4 to C4b and reduced C4b and C3b deposition on cell surfaces.²⁴ Soluble NS1 has also been reported to bind the complement regulatory factors

C4bp²⁵ and clusterin, the latter of which normally inhibits the formation of the C5b–C9 membrane attack complex.⁴³⁹

Class I MHC and NK Cell Evasion. Because of their capacity to directly kill virally infected cells or produce inflammatory cytokines that control early stages of infection, NK cells are an important initial defense against many viruses. NK cells lyse infected cells by releasing cytotoxic granules that contain perforin and granzymes, or by binding to apoptosis-inducing receptors on target cells. NK cell activation is finely regulated through a balance of activating (Ly49D, Ly49H, and NKG2D) and inhibitory cell surface receptors (killer-cell immunoglobulin-like receptors (KIRs), immunoglobulin-like inhibitory receptors (ILTR), and CD94–NKG2A). To control the consequences of untoward activation of NK cells, inhibitory receptors are expressed constitutively, some of which bind to host MHC class I molecules on opposing cells and transmit inhibitory signals through intracellular tyrosine-based inhibitory motifs in their cytoplasmic domains. A decrease in expression of class I MHC molecules on a cell may prompt NK cell activation by attenuating the inhibitory signals. Therefore, NK-cell target recognition occurs after ligation of activating receptors and repression of inhibitory receptors on the cell surface.

Although many viruses attempt to avoid NK responses by expressing MHC class I homologs, flaviviruses may evade NK cell cytotoxicity by increasing surface expression of class I MHC molecules.^{400,493,494} Expression of class I MHC molecules is stimulated by increasing the transport activity of transporter associated with antigen processing (TAP)^{561,592} and by NF- κ B-dependent transcriptional activation of MHC class I genes.³⁸⁹ The rapid increase in expression of MHC class I suggests that early in the course of infection, flaviviruses may overcome susceptibility to NK cell-mediated lysis, even if it is at the expense of later recognition by an adaptive CD8⁺ T-cell response. Consistent with this, splenocytes from WNV-immunized mice had poor NK-cell lytic activity⁵⁶¹ and mice with acquired deficiencies in NK cells demonstrated no increased morbidity or mortality compared to wild type controls.⁷⁵⁵

Intrinsic ADE. The ligation of monocyte or macrophage Fc- γ receptors by IgG immune complexes, rather than aiding host defenses, have been hypothesized to suppress innate immunity, increase production of IL-10, and bias T-helper cell responses, leading to increased infectious output by infected cells.^{304,587} Initial studies with the unrelated Ross River alphavirus in RAW 264.7 macrophage-like cells showed that infection by ADE suppressed expression of CXCL10, NOS-2, IRF-1, TNF- α , and IFN- γ .^{472,515} Subsequent experiments with DENV in the THP-1 monocytic cell line confirmed that ADE attenuated innate immune responses by downregulating the RIG-I/MDA5 signaling pathway and decreasing production of type I IFN and ISGs.⁸³⁷ However, more recent experiments with DENV infection of primary human monocytes^{86,419} did not demonstrate suppressed production of inhibitory or immunomodulatory cytokines in the context of ADE. One caveat to the concept of intrinsic ADE is that enhanced viral entry and infectivity (via DENV immune complex interaction with Fc- γ receptor) yields higher levels of viral nonstructural proteins in a cell, which themselves independently suppress innate immunity^{197,198} irrespective of Fc- γ receptor signaling. Although the idea that intrinsic ADE of infection suppresses

innate immunity and modulates disease severity of DENV infection is appealing,³⁰⁴ it remains to be distinguished from the enhanced infectivity *per se* and confirmed in a physiologically relevant setting.

ANIMAL MODELS OF FLAVIVIRUS PATHOGENESIS AND DISEASE

Animal models of viral infections are used to address fundamental questions that are difficult to answer in human studies. These investigations are often directed toward defining basic mechanisms of viral pathogenesis (tropism, dissemination, and virulence) and host immune responses (protective and pathologic), but also are important for determining relative efficacy of candidate vaccines and antiviral agents. Although what constitutes a good animal model varies among investigators, in general, the most useful surrogate models mimic features of human disease, are reproducible, and have the capacity for high-throughput experimentation. The weakness of many animal models is they often do not fully recapitulate human disease with respect to kinetics, viral replication and spread, or disease phenotype, and thus restraint is required in applying these results to the human condition. Animal models of flavivirus infection are varied in their fidelity to human disease, and thus in their utility in providing basic insight into pathogenesis, immune control, and likely efficacy of vaccines or antiviral agents. This section reviews the strengths and weaknesses of key animal models, and what investigators in the field have learned by using them.

Dengue Virus

One of the major limitations in identifying and working with animal models of DENV infection is that humans are the only known host to develop disease after infection. A second consideration is that severe DENV infection and its plasma leakage syndrome is associated with preexisting maternal antibody in infants and secondary infection in children and adults, suggesting an immunopathogenesis mechanism, which has been difficult to recapitulate in animals. Although each of the animal models described below has been informative for understanding DENV infection, their inability to mimic human disease has limited the insight on human DENV infection.

Non-Human Primate Model of DENV Infection

Although humans are the natural host for DENV, serologic data support the existence of a sylvatic cycle between mosquitoes and nonhuman primates (NHPs).⁸⁵⁷ Several species of monkeys (e.g., chimpanzees and rhesus macaques) have been infected experimentally with DENV and develop viremia and adaptive immune responses,^{308,309,718} although in most cases, there is limited evidence of the severe disease seen in humans. One study in macaques showed thrombocytopenia, transiently reduced complement levels, and enhanced peak viremia after secondary infection with heterologous DENV serotype, although only 1 of 44 animals developed a syndrome that shared features of severe human disease.³⁰⁹ A more recent study observed features of DHF in six rhesus macaques after high-dose (10^7 PFU per animal) intravenous infection with a DENV-2 strain,⁶³² including neutropenia, thrombocytopenia, clotting abnormalities, and petechial hemorrhage.

In addition, NHPs have been used as a model to study ADE and its consequences *in vivo*. *In vivo* enhancement of viremia was observed in juvenile rhesus monkeys after passive transfer of antibody and heterologous DENV challenge.²⁹⁷ Analogously, an approximately 100-fold increase of DENV-4 viremia was demonstrated in juvenile rhesus monkeys that received a cross-reactive mAb recognizing the fusion loop in DII.²⁶⁵ In neither model, however, was evidence of severe vascular leak observed despite the increase in DENV replication. NHPs also have been used to evaluate adaptive immune response and protection of live-attenuated or subunit-based DENV vaccine candidates.^{158,213,418}

Mouse Models

A recent review describes the utility and clinical features of individual mouse models of DENV infection in great detail (see Table 1 in Yauch and Shresta⁹⁰²). Below, we describe some features of the more commonly used models in the field. In general, there have been several hurdles to establishing mouse models of DENV disease pathogenesis: (a) the majority of models are not ideal because most mice do not develop the same clinical disease as humans; (b) it has been difficult to infect mice reliably and reproducibly with low passage clinical and mosquito isolates (hence, many studies are performed with laboratory- or mouse-adapted strains that have uncertain relevance to the strains that cause human disease); and (c) DENV is virulent in humans because it has evolved specific countermeasures to evade the human immune response.¹⁹⁸ In mice, these evasion mechanisms may not function, resulting in rapid control. One example is the recent finding that DENV NS5 promotes degradation of human but not mouse STAT2, a key protein in the type I IFN signaling cascade.²¹

IFN-SIGNALING DEFICIENT MICE

Because of the importance of STAT2 and the IFN response in restricting DENV infection, mice (AG129) lacking receptors for both type I (IFN- α/β) and type II (IFN- γ) were tested and shown vulnerable to intraperitoneal (i.p.) infection with a mouse-adapted (New Guinea C) DENV-2 strain³⁶⁰ or intravenous (i.v.) infection with a laboratory-adapted (PL046) DENV-2 strain.⁷⁴⁸ In these studies, however, mice succumbed to DENV infection because of rapid spread to the CNS, resulting in encephalitis and paralysis, which are not common features of human disease. Similar results were observed in STAT1^{-/-} mice,⁷⁴⁹ although in some cases hemorrhage was observed after inoculation at multiple sites.¹⁴⁴ Subsequent investigation identified mouse adapted (DENV-2 D2S10) and nonadapted strains (DENV-2 Y98P) that cause rapid death of AG129 mice associated with some characteristics of human disease, including cytokine storm, vascular leakage, and high TNF- α levels^{750,808} after i.v. or i.p. infection.

AG129 mice have been used as a model to test antiviral candidates^{148,737,782} or to explore the role of ADE in disease severity. Two groups showed that preexisting cross-reactive monoclonal or polyclonal antibody facilitate ADE *in vivo* and promote more severe DENV disease including vascular leakage.^{39,912} Importantly, when the Fc fragment of the antibody was eliminated by proteolysis or modified genetically, enhanced replication and disease were no longer observed, thus confirming the longstanding hypothesis that ADE can cause severe disease in an animal.²⁹⁹ Cellular and tissue tropism have been

examined in the ADE model in AG129 mice^{39,912}; the virus targets appear similar to that described in human autopsy studies, with antigen present in the lymph node, spleen, and bone marrow, with significant infection in myeloid cells, and possibly sinusoidal endothelial cells in the liver. Although the comparative data are intriguing, the absence of IFN in mice independently broadens cellular and tissue tropism of flaviviruses,⁷⁰⁴ and thus some caution in interpretation is warranted.

IMMUNOCOMPETENT MICE

The successful infection of immunocompetent mice with DENV strains would allow more detailed analysis of the kinetics and function of protective immune responses. Although most DENV strains replicate poorly in wild-type laboratory strains of mice, recent reports suggest that infection may be possible, with the development of a spectrum of disease. Subcutaneous and systemic hemorrhage was induced in wild-type C57BL/6 mice after intradermal (i.d.) infection with a laboratory passaged DENV-2 16681 strain.¹⁴¹ With this strain, C57BL/6 and BALB/c mice also developed thrombocytopenia, elevated levels of systemic TNF- α , and liver damage.^{142,635} However, none of these experiments showed evidence of vascular leakage, the hallmark of severe DENV disease in humans. Studies with a mouse-adapted DENV-2 strain (P23085) that was injected i.p. in 4 week-old BALB/c or C57BL/6 mice showed thrombocytopenia, liver injury, and the development of a vascular permeability and shock-like syndrome.^{23,774} This promising mouse model, which has not yet been validated extensively, recently was used to assess the function of platelet-activating factor, macrophage migration inhibitory factor, and chemokine receptors in the pathogenesis of DENV.^{22,283,774}

MOUSE-HUMAN CHIMERAS

Because most mouse strains do not sustain DENV replication after infection, mouse-human chimeras have been developed. Early studies using severe combined immunodeficient (SCID) mice engrafted with human peripheral blood lymphocytes showed marginal infection with a DENV-1 strain.⁸⁹⁴ Subsequent studies engrafted human tumor cells (K562, HepG2, Huh-7),^{12,80,486} which supported DENV replication but caused CNS disease and not a vascular leakage syndrome. Nonobese diabetic (NOD)/SCID or NOD/SCID IL2R γ ^{-/-} have been engrafted with CD34⁺ human cord blood hematopoietic progenitor cells. After infection with DENV-2, these chimeric mice developed some of the signs of severe human disease including fever, rash, and thrombocytopenia.^{65,357,589} In an analogous model, RAG2^{-/-} x γ chain^{-/-} mice engrafted with CD34⁺ human fetal liver stem cells and infected with DENV-2, developed viremia and fever and produced human-specific anti-DENV antibody responses.⁴⁴⁰ Although engraftment of human cells is advantageous as the response of human cells, pathogenesis, and possibly tropism can be analyzed, the chimeric models have limitations: (a) the disease phenotype generated to date recapitulates only some of the features of severe DENV; (b) technically, the mouse-to-mouse level of chimerism is variable, making phenotypic analysis challenging; (c) the throughput of experiments is low, making these models less practical for vaccine or antiviral testing; and (d) the immune cross-talk between human and mouse cells within an animal may be altered, limiting interpretation of effects on immunity.

Yellow Fever Virus

Despite the fact that YFV was isolated in 1927 and that a vaccine was developed 10 years later, our understanding of the mechanisms underlying the virulence and pathogenesis of virulent YFV remains surprisingly limited. Analogous to DENV, part of this stems from the lack of a small animal model that recapitulates the viscerotropism of human infection. Given the reemergence of YFV, an improved understanding of its pathogenesis and a vehicle for testing novel vaccines and antiviral agents through the use of existing and new animal models of disease is now a research priority.

Human Vaccine Model

Vaccination with the attenuated 17D strain of YFV has conferred protection to hundreds of millions of humans worldwide. Recent prospective analyses have examined the interaction of 17D YFV with the innate immune system and how this might be important for triggering long-term protective adaptive immunity.⁶⁶¹ A systems biology approach defined early gene signatures that predicted immune responses in humans vaccinated with yellow fever vaccine YF-17D. Computational analyses identified induction of genes (e.g., complement protein C1qB, TNFRS17, and eukaryotic translation initiation factor 2 alpha kinase 4) that correlated with and predicted protective B- and T-cell responses with high accuracy in an independent, blinded trial.⁶⁶⁸

Nonhuman Primate Model of Severe YFV Infection

YFV cycles in nature as part of a sylvatic cycle between *Aedes* mosquitoes and wild monkeys. Rhesus and cynomolgus monkeys develop viscerotropic disease, analogous to humans, ranging from mild to fulminate hepatitis, whereas African and New World NHPs have milder or silent infections.⁵⁶⁷ The pathogenesis of YFV infection in rhesus monkeys resembles severe human disease with the development of jaundice, acute renal failure, coagulopathy, and shock,⁵⁶⁸ although the course is more severe, not biphasic, produces markedly higher viral burden, and is also associated with severe necrosis of lymphoid tissue.^{409,568} The coagulopathy in monkeys is associated with a global decrease in synthesis of clotting factors secondary to direct hepatic damage and impaired hemostasis associated with abnormalities of platelet function.⁵⁶⁷

In contrast to that described for DENV, preexisting immunity to heterologous flaviviruses results in protection rather than enhanced pathogenesis in NHPs. Rhesus monkeys that were infected previously with DENV were protected against YFV challenge, and recipients of anti-DENV antibodies by passive transfer showed no evidence of enhanced disease.^{567,818} Monkeys immunized with other flaviviruses,³²⁶ similar to humans with prior exposure to flaviviruses,⁵⁷⁰ manifest a lower incidence of severe YFV disease.

Rodent Models of YFV Infection

Historical infection studies in mice and hamsters with non-adapted YFV did not cause viscerotropic disease. Syrian golden hamsters, however, did develop disease that more closely resembled human YFV infection (hepatitis, hepatic necrosis, splenic necrosis), but this phenotype requires serial passage of YFV *in vivo*, and renal disease was not observed.^{539,897} In comparison, peripheral infection of wild-type mice does not cause viscerotropic disease. However, YFV-induced encephalitis can be

induced in suckling mice after i.p. or intracranial (i.c.) inoculation, in adult mice if the blood-brain barrier is disturbed, or if mouse-adapted strains are used.^{44,236,237,567,711} Because these models do not cause viscerotropism, they are of limited relevance to understanding the pathophysiology of human YFV infection, and have been largely restricted to vaccine and antiviral testing. More recent subcutaneous infection studies of mice that are deficient in IFN-signaling revealed viscerotropic YFV infection and disease (liver and spleen necrosis) without a requirement for virus adaptation.⁵⁴⁸ This study suggests that nonadapted YFV has little ability to evade the antiviral activity of IFN- α/β in mice, whereas species-specific antagonism of IFN- α/β antiviral activity in primate hosts may contribute to infection outcome.

West Nile Virus

WNV and other encephalitic flaviviruses are generally more promiscuous in their ability to infect and cause disease in different species of animals. Beyond its endemic cycle in multiple species of birds, WNV causes severe disease in horses, and can periodically infect other mammals sometimes with severe consequences.⁹¹ Although the molecular basis for its broad animal tropism remains uncharacterized, as a result of this, it has been easier to develop animal models of infection that recapitulate features of human disease using low-passage field isolates. However, the frequency of neuroinvasive disease may vary significantly among animal strains, making some models preferred for studying pathogenesis and disease outcome.

Non-Human Primate Model of WNV Infection

NHP models of WNV infection are important because of their potential for use in evaluating vaccine and therapeutic candidates. In one study of five intradermally infected rhesus macaques, the clinical course, level and duration of viremia, and antibody response were similar to that occurring in uncomplicated human WNV infection, although it was unclear whether virus entered the brain in these animals.⁶⁷² This model of sustained viremia and measurable immune responses has been used to evaluate the efficacy of WNV vaccine candidates.⁸⁸⁴ Analogously, in baboons, after intradermal infection, WNV accumulated to high levels in blood and was associated with a transient macular rash, but failed to cause encephalitis or other severe clinical signs.⁸⁸⁹ Although these NHP models do not develop WNV encephalitis, it remains possible that the frequency of neuroinvasive disease parallels human infection (1:150), and thus would require much larger studies to identify severe cases. In contrast to infection via a peripheral route, i.c. inoculation of rhesus monkeys with different African and Asian WNV strains results in persistent viral infection in the CNS and other organs.⁶⁵⁵ These animals sustained a prolonged infection course and showed evidence of fatal encephalitis with diffuse neuronal degeneration and necrosis and inflammation. Similar severe clinical manifestations (fever, tremors, and spasticity) were observed in rhesus macaques challenged via a frontal lobe injection with the New York 1999 strain of WNV.¹⁹

Hamster Model

Syrian golden hamsters are an excellent small animal model for studying WNV pathogenesis, vaccine efficacy, and antiviral screening. Intraperitoneal or even oral infection of a New York isolate of WNV results in viremia of 5 to 6 days in duration,

followed by the development of virus-specific antibodies.^{714,896} Clinical signs of encephalitis (weakness, tremor, ataxia, and paralysis) were apparent within 6 to 7 days of infection with an approximately 50% mortality rate. WNV disease correlated with the detection of viral antigen and neuronal degeneration in several regions of the brain including the cerebral cortex, basal ganglia, hippocampus, cerebellum, and brainstem. Because of their larger size relative to mice, hamsters have been used to elucidate particular aspects of neuropathogenesis. WNV spread to the CNS can occur through a retrograde axonal transport mechanism as the virus moves from peripheral motor neurons into the spinal cord.^{705,860} Electrophysiology studies have shown that respiratory distress associated with WNV infection is caused by diaphragmatic suppression through lesions in the brainstem and cervical spinal cord, or altered vagal afferent function.⁵⁸³

In the hamster model, infectious WNV can be cultured from the brains of hamsters up to 53 days after initial infection,⁸⁹⁶ suggesting that persistent replication occurs. Persistent WNV infection or protein production in the spinal cord causes continued neuronal dysfunction, chronic neuropathologic lesions, and poliomyelitis-like disease, and can be measured using electrophysiologic approaches.⁷⁵⁸ Consistent with persistent infection in the brain, hamsters also develop persistent viruria, as infectious WNV can be cultured from urine for several weeks.⁸²⁶

The hamster model has been used to evaluate candidate therapeutics or vaccines against WNV disease. Studies with small molecule inhibitors,⁵⁸⁶ antiviral cytokines,⁵⁸⁰ synthetic oligonucleotides,⁸²⁷ and humanized monoclonal antibodies⁵⁸¹ have been performed with varying efficacy, especially when administered as postexposure therapy.¹⁹⁹ Analogously, immunization with single-cycle,⁸⁸⁵ recombinant subunit,⁷⁶¹ or live-attenuated⁸¹⁵ vaccines have elicited durable protective immunity, and thus has provided a robust preclinical small animal model for assessment and comparison of the surrogate markers of protection.

Mouse Models

Infection studies in several inbred laboratory strains of mice have provided insight into the fundamental mechanisms of WNV dissemination, pathogenesis, and immune system control. Over the last decade, most studies have been performed with North American WNV strains and wild-type and immunodeficient strains of C57BL/6 mice. The strengths of this particular model include the following: (a) depending on the dose of virus and age of mice, a subset of wild-type mice develop neuroinvasive disease, whereas the remainder are infected with minimal or limited spread to the CNS. Therefore, the mechanisms by which the immune system restricts viral entry or facilitates viral clearance can be studied; (b) many features of pathogenesis and neuropathology appear remarkably similar to that observed in humans; (c) nonadapted low-passage WNV isolates cause disease in wild-type mice. Therefore, this model can be used to define the genetics of virus attenuation; (d) there are a large number of transgenic, knockout, and conditional knock-out mice available from academic laboratories and public consortia to study the role of specific genes or cells in pathogenesis; and (e) genes (e.g., CCR5 and OAS-1b) that predict susceptibility in mice have been corroborated as risk factors for human WNV disease.²⁰¹ Nonetheless, there are limitations to

the model including the compressed disease time course, the difficulty in obtaining CSF samples in live animals because of size, and a rather flat virus dose–response curve after peripheral infection. Moreover, the mouse anti-WNV antibody response appears directed at a distinct dominant neutralizing epitope than the human response.⁶²⁸

Following peripheral inoculation of mice, initial WNV replication is thought to occur in keratinocytes and skin Langerhans dendritic cells,¹¹⁷ with mosquito saliva modulating the local proinflammatory cytokine response.⁷³⁰ Dendritic cells migrate to and seed draining lymph nodes, resulting in a primary viremia and subsequent infection of peripheral tissues such as the spleen and occasionally, the kidney. By the end of the first week, WNV is largely cleared from the serum and peripheral organs, and infection in the CNS is observed in a subset of immunocompetent animals. Mice that succumb to infection develop CNS pathology similar to that observed in human WNV cases, including infection and injury of brainstem, hippocampal, and spinal cord neurons.⁷⁵⁴ WNV infection is detected at much lower levels in nonneuronal CNS cell populations, such as CD11b⁺ cells^{176,828} or astrocytes.²⁰⁸ In most surviving wild-type mice, WNV is cleared from all tissue compartments within 2 to 3 weeks after infection. However, persistent WNV infection in the brains of class II MHC,⁷⁶⁵ CD8⁺ T-cell⁷⁵² or perforin deficient mice⁷⁵⁵ was routinely observed. Analogously, a small subset of wild-type mice sustained WNV persistence in the CNS, even in the setting of a robust antibody response and inflammation.¹⁶ Remarkably, WNV persistence in the CNS was observed even in mice with subclinical infections, as treatment with the immunosuppressive drug cyclophosphamide resulted in active viral replication.

PREVENTION AND CONTROL

Flavivirus Vaccines

Successful vaccination programs have dramatically reduced the global health burden of flavivirus infections. More than 500 million doses of vaccine to prevent YFV infection have been administered since its development in 1937, and effective vaccines have blunted the impact of JEV and TBEV as discussed below. Nonetheless, safe and effective vaccines for several clinically significant flaviviruses still remain elusive. As an example, up to 100 million DENV infections occur each year, and severe disease manifestations are occurring with an increased frequency.⁸⁸² New flavivirus vaccines and improvement on safety of existing vaccines is urgently needed. The development of molecular clone technology, more sophisticated animal models of infection, and insights from structural biology have aided recent efforts in these areas.

Yellow Fever Virus

The live-attenuated YFV 17D vaccine is considered among the most safe and effective ever developed, an achievement for which Max Theiler was awarded the Nobel Prize in 1951. An excellent historical account of the development of this vaccine has been written by Monath.⁵⁶⁹ The current YFV vaccine was derived from a virus (the Asibi strain) isolated in 1927 from a West African man with a mild febrile illness.⁷⁸⁹ The Asibi strain was passaged 176 times in the embryonic tissue of mice and chickens to yield the YF-17D virus with considerably reduced

neurotropic and viscerotropic properties.^{565,819} Vaccines currently in use are substrains of YF-17D; strain YF-17DD is used in vaccines produced for South America (passage 287–289), whereas the YF-17D-204 strain (passages 235–240) is distributed elsewhere, including the United States.^{46,779} The consensus sequence of the vaccine strains differs from the parent Asibi strain by approximately 20 amino acids as well as by 4 nucleotide changes in the 3' UTR.⁵⁶⁵ Vaccine is produced in chicken embryos, lyophilized, and administered by subcutaneous injection following reconstitution in saline. A single dose of YFV vaccine contains roughly 10^4 to 10^6 PFU.⁴⁶

THE IMMUNE RESPONSE TO YF-17 INFECTION

The host response to YF-17D infection involves both the adaptive and innate arms of the immune system.⁵⁶⁹ Recent studies highlight the significance of the innate response to YF-17D in shaping the adaptive immune response to vaccination.^{247,661,667} YF-17D activates mDCs and pDCs through multiple TLR proteins, including TLR2, TLR7, TLR8, and TLR9, resulting in the induction of proinflammatory cytokines and IFN- α .^{667,668} Of interest, a capacity to interact with multiple TLR pathways does not appear functionally redundant; these interactions tune the adaptive response by influencing the balance of Th1 and Th2 cytokines and the quality of the anti-YFV T cell response.⁶⁶⁷ Indeed, YF-17D infection induces a mixture of Th1 and Th2 cytokines *in vivo*,^{247,709} and YF-17D infected DCs present viral antigen to T cells despite inefficient replication in these cells.^{40,636}

YF-17D vaccination induces a low-grade and transient viremia that peaks on day 5.⁵⁶⁵ Defervescence is coincident with a reduction in viremia and the detection of cellular and humoral responses. YF-17D infection induces a polyfunctional CD8⁺ T-cell response of considerable magnitude (2% to 13% of CD8⁺ T cells) that peaks roughly 2 weeks postimmunization.³ Analysis of the breadth of this response demonstrates that all 10 viral proteins contain epitopes recognized by CD8⁺ T cells; reactivity with epitopes in E, NS3, and NS5 proteins were most common.^{4,247} The virus-specific CD8⁺ T-cell response contracts at approximately day 30 postinfection to a size that corresponds to approximately 5% to 10% of the magnitude of the original response, with memory CD8⁺ T cells persisting for years.^{4,555}

Vaccination with YF-17D also elicits a rapid neutralizing antibody response in virtually all recipients.^{60,645} Kinetic analysis of vaccinated adults revealed that approximately 87% have neutralizing antibodies at 2 weeks postvaccination, with virtually 100% of subjects developing neutralizing antibody by day 28.⁴⁴⁸ YFV-reactive IgM can be detected by day 9, peaks between days 14 and 17, and persists for more than one year. YFV-specific IgG is detected between days 10 and 17 and peaks approximately 1 month postvaccination.⁵⁶⁹ Neutralizing antibodies persist for decades. More than 90% of vaccinated subjects had neutralizing antibody when examined 16 to 19 years postimmunization.⁶⁹³ Indeed, neutralizing antibody was detected in 80% of vaccinated U.S. military personnel when assayed 30 to 35 years after receiving YF-17D.⁶⁵⁶ Despite the impressive longevity of the antibody response, booster immunizations are still recommended every 10 years.⁷⁷⁹

The neutralizing antibody response correlates with protection from infection.^{60,533,569,575} Roughly 94% of primates with a neutralizing antibody titer greater or equal to 0.7 logs (1/5

dilution of serum) were protected from a lethal challenge with YF-Asibi.⁵³³ As a comparison, the mean neutralizing antibody titer of recipients of the YF-17D vaccine at 28 days postimmunization is 2.2 logs (1/160 serum dilution).⁵⁷⁵

ADVERSE EVENTS ARISING FROM YF-17D VACCINATION

More than 500 million doses of YF-17D have been administered to humans with a high track record of safety.²⁴⁶ The most common side effects from YF-17D vaccination are transient headache, myalgia, and low-grade fever.⁷⁷⁹ Severe adverse events (SAEs) following vaccination have been reported, albeit at a very low frequency. The risk of SAEs following vaccination increases with age; the incidence of SAEs in vaccine recipients greater than 70 years of age is roughly 10-fold higher than that for individuals aged 19 to 29.³⁹¹ Three main classes of SAEs have been reported:

1. Anaphylactic reactions are infrequent (1 in 135,000) and likely a result of allergic responses to components of the vaccine including egg and chicken proteins, gelatin, and latex.^{387,779} Hypersensitivity to eggs is a contraindication for vaccination.⁵⁶⁹
2. Vaccine-associated neurologic disease (YEL-AND) is associated with invasion of the CNS by the vaccine strain. This SAE was most commonly reported prior to the establishment of the vaccine seed system (in 1945) and in infants prior to changes in the recommendations for vaccination of children less than 6 months old (in 1960).⁵⁶⁵ The mechanism underlying the increased risk of YEL-AND in infants remains uncertain, but may reflect differences in the level or duration of viremia, the integrity of the BBB, or a failure to mount an effective immune response.⁵⁶⁹ Twenty-nine cases of YEL-AND have been reported since 1990 with a case fatality ratio of 6.9%⁵⁶⁹ with an incidence of 0.4 to 0.8 per 100,000 doses.^{487,779}
3. Vaccine-associated viscerotropic disease (YEL-AVD) is a recently reported SAE that mimics many aspects of naturally acquired YFV infection. YEL-AVD is characterized by the rapid onset of high fever (within 2 to 5 days of vaccination), malaise, and myalgia that is followed by jaundice, oliguria, cardiovascular instability, and hemorrhage. Analysis of the sequence of viruses recovered from vaccine recipients with YEL-AVD failed to identify mutations associated with this SAE.⁴⁶ Risk factors for YEL-AVD include advanced age and a history of thymus disease or thymectomy. As of 2010, 57 cases of YEL-AVD have been reported with a case fatality rate of 64%. In the United States, the incidence is estimated as 0.3 to 0.5 per 100,000 doses.⁷⁷⁹

NEW VACCINE APPROACHES

Despite the demonstrable success of the live-attenuated YF-17D vaccine, the potential for SAE has prompted efforts to develop new vaccines with improved safety. Perspectives supporting a need for new vaccine approaches have been given.³¹⁶ A new inactivated whole virus vaccine candidate, XRX-001, is being developed to complement the existing YF-17D vaccine, particularly for contraindicated populations. XRX-001 is a β -propiolactone inactivated YF-17D virus that is produced in Vero cells and adsorbed to aluminum hydroxide.⁵⁷³ Two doses of vaccine in the presence or absence of adjuvant was sufficient to elicit a neutralizing antibody response in mice. The neutralizing

antibody titers achieved following XRX-001 vaccination were equivalent or better than those with live-attenuated YF-17D vaccination experiments performed in parallel. Experiments in hamsters and NHPs confirmed that vaccination protected against lethal challenge with YFV.⁵⁷³ Evaluation of this candidate vaccine in human clinical trials is underway (clinical trials.gov identified NCT00995865).

Dengue Virus

Four antigenically related serotypes of DENV circulate in nature. Although natural infection by DENV is thought to confer protection from re-infection by a homologous DENV serotype,⁷⁰⁰ an increased risk of severe clinical manifestations following secondary infection by a heterologous DENV has been demonstrated.^{112,224,294,305} Therefore, the potential for an exacerbated clinical outcome in a DENV sensitized-individual complicates the development of a safe and effective vaccine. A perceived requirement of candidate DENV vaccines is that administration confers simultaneous, durable protection against all four different DENV serotypes. Given the considerable effort and resources required to bring a safe and effective vaccine against a single pathogen to market, a tetravalent DENV vaccine is among the most ambitious vaccine development efforts undertaken. DENV vaccine research traces its roots to the 1940s⁷⁰¹ and has advanced from empirical administration of passaged strains to rational design that exploits the advances of molecular and structural virology.²¹⁷

LIVE ATTENUATED DENGUE VACCINES DERIVED FROM EXTENSIVE PASSAGING

The earliest efforts to produce a vaccine against DENV were undertaken by Sabin and colleagues.⁷⁰¹ DENV-1 (Hawaii strain) was passaged in mice via intracranial inoculation, isolated as a brain homogenate, and used to challenge human volunteers. Although the first six passages of DENV in mice did not sufficiently attenuate the virus and caused fever in human subjects, experiments with virus passaged seven or more times conferred protection following challenge with DENV-infected mosquitoes.^{700,701} Similar experiments were performed using the DENV-1 Mochizuki strain.^{340,341} A more extensively passaged mouse brain-derived DENV-1 isolate was the first DENV vaccine candidate evaluated in the field during an outbreak of DENV-3 in Puerto Rico; this heterologous protection experiment suggested an efficacy of about 40%.^{59,703}

Extensive passage in tissue culture also has been used to attenuate DENV for use in vaccines. Investigators in Thailand developed vaccine candidates for all four serotypes of DENV via serial passages in primary dog kidney (PDK) or primary green monkey kidney (PGMK) cells.⁸⁸² Aventis Pasteur/Sanofi Pasteur licensed these strains for clinical vaccine development. The safety and immunogenicity of tetravalent formulations was investigated in clinical trials in adults^{376,696} and in children.⁶⁹⁷ Although these vaccines were generally well tolerated, reactogenicity was noted, particularly after the first dose of vaccine. Furthermore, the DENV-3 component of the vaccine replicated more robustly in vaccinated subjects and was immunodominant. Although changes in the relative doses of each component strain of the vaccine were tested to reduce the dominance of DENV-3 and reactogenicity, development of this tetravalent candidate was halted. These studies highlight the complexity and challenge of eliciting a balanced immune

response against four different viruses representing all DENV serotypes.

Investigators at the Walter Reed Army Institute of Research (WRAIR) developed a tetravalent vaccine composed of four highly passaged DENV. These viruses were produced by serial passage of clinical isolates of DENV in PDK cells, and the formulation of candidate tetravalent vaccines were studied in several monovalent and tetravalent clinical trials.²¹⁷ A phase I clinical evaluation of two doses of vaccine administered 6 months apart demonstrated that the vaccine was well-tolerated and elicited a tetravalent neutralizing antibody response in all subjects.⁷⁶³ Concerns as to the durability of the tetravalent humoral response in humans has prompted the commercial partner (GlaxoSmith-Kline) to suspend clinical trials (J Toussaint, personal communication) with this vaccine candidate.

LIVE-ATTENUATED DENGUE VACCINES: RATIONAL DESIGN USING MOLECULAR BIOLOGY

The development of molecular infectious clones of flaviviruses has enabled the construction and characterization of variants with attenuating mutations. The 3' UTR of flaviviruses folds into RNA structures that function to regulate genomic RNA replication, translation, and cytopathicity.^{159,649} The introduction of a 30 nucleotide deletion in the 3' UTR of DENV-4 (strain 814669) yielded a markedly attenuated virus *in vivo*, which still elicited a robust humoral response in monkeys and humans.^{213,550} Vaccination with DENV-4Δ30 resulted in low-level viremia (~1.6 logs) in 70% of recipients,²¹³ which is not sufficient for blood-meal transmission of the vaccine to mosquito vectors. Similar results were reported with a DENV-1Δ30 virus constructed from the Western Pacific 1974 strain.²¹⁴ In contrast, DENV-2 and DENV-3 viruses incorporating the Δ30 deletion were not attenuated sufficiently to warrant further study as vaccine candidates.^{78,79} A second DENV-3 virus, however, encoding two deletions in the 3' UTR (DENV-3Δ30/31) appears more promising; monkeys immunized with this variant were not viremic, mounted a robust neutralizing antibody response, and were protected from challenge by wild-type virus.⁸²

The development of chimeric flaviviruses encoding the structural genes of heterologous viruses is a second attenuation approach that has yielded several promising vaccine candidates. The first chimeric viruses were constructed by introducing the C, prM, and E genes of DENV-1 or DENV-2 into the genetic background of DENV-4.⁹⁵ These viruses were immunogenic and attenuated as immunization of monkeys elicited neutralizing antibodies and reduced viremia following challenge with a homologous wild-type strain.⁹⁶ These early studies established that the structural proteins conferred the serologic specificity of chimeric DENV. Chimeric vaccine candidates encoding the heterologous C-prM-E and prM-E cassettes have been characterized; viruses constructed using the latter replicated more efficiently than those encoding all three structural genes, perhaps due to a requirement for interaction between RNA elements in the capsid gene and the 3' UTR.⁹⁶ Several tetravalent chimeric flavivirus vaccine candidates using molecular backbones of DENV4Δ30, YF-17D, and DENV-2 viruses are in advanced stages of clinical development.^{446,597}

A tetravalent DENV vaccine using chimeras constructed with the DENV-4Δ30 backbone is being developed by the National Institute of Allergy and Infectious Disease (NIAID),

National Institutes of Health (NIH). Because the DENV-4 backbone of these viruses is already attenuated by the $\Delta 30$ deletion, viruses were constructed using the structural genes from wild-type strains. A chimeric DENV-2/DENV-4 $\Delta 30$ virus encoding the prM-E of the New Guinea C DENV-2 strain has been evaluated in phase I clinical studies.^{215,883} Although chimeric DENV4 $\Delta 30$ encoding the structural proteins of DENV-3 could be recovered, these viruses were over-attenuated *in vivo*.⁷⁸ A second chimeric virus strategy involved replacing the 3' UTR of a DENV-3 virus with the DENV-4 $\Delta 30$ UTR described above is being evaluated.⁸² Tetravalent formulations of the NIAID vaccine candidates are in phase I clinical trials and include both chimeric viruses and those encoding a $\Delta 30$ deletion.

Because of the extensive safety profile of the YF-17D vaccine, several chimeric viruses also have been constructed by replacing genes encoding the structural proteins of YF-17D with those of heterologous flaviviruses.²⁹² This platform, called ChimeriVax™ (licensed by Sanofi Pasteur), has been used to create chimeric viruses expressing the prM-E proteins of all four serotypes of DENV.²⁸⁴ The structural genes of these chimeric viruses were obtained from low-passage primary isolates of human dengue cases. Preclinical and clinical studies demonstrate that ChimeriVax-DENV is safe, with minimal and nonsevere adverse reactions (reviewed by²⁹²). Studies in suckling mice infected via the intracranial route demonstrated that chimeric DENV-YF-17D has lost the neurovirulent phenotype associated with the YF-17D backbone. Vaccination of monkeys and humans results in a low and transient viremia of reduced magnitude compared to the parental viruses. Preclinical studies in monkeys immunized with a single dose of a tetravalent formulation showed excellent immunogenicity, and 92% percent of immunized animals remained aviremic after challenge with wild-type DENV.²⁸⁷ A randomized phase IIb study of this vaccine candidate in dengue-experienced subjects (clinicaltrials.gov identifier NCT00842530) revealed only modest efficacy (30.2%) that was not uniform among serotypes; no protection against infection by DENV2 viruses.^{697a}

A third chimeric tetravalent DENV vaccine formulation has been generated using the Thai DENV-2 PDK-53 vaccine strain as the backbone.^{345,346} Although these vectors are immunogenic and protective in mouse models, they have only recently entered phase I clinical trials in humans (clinical trials.gov identifier NCT01110551).

ALTERNATIVE VACCINE STRATEGIES

DNA Vaccines. DNA-based DENV vaccines offer several advantages including ease of production, transport, and storage. Furthermore, administration of multiple DNA constructs encoding different flavivirus antigens avoids viral interference.⁷²⁶ The first DNA vaccine for DENV encoded the prM and a secreted form of the E protein lacking the transmembrane domains of the DENV-2 New Guinea C strain.⁴¹³ Plasmids that express prM and E proteins may be particularly immunogenic, as they can produce secreted subviral particles *in vivo*, which display the E protein in a highly ordered array analogous to that present on infectious virions.²³³ Two vaccinations with four plasmids encoding the envelope proteins of each DENV serotype were sufficiently immunogenic in mice to confer protection from heterologous challenge with any of the four dengue viruses.⁴¹⁷ However, a phase I clinical evaluation of three

doses of a monovalent DENV-1 DNA vaccine revealed only modest immunogenicity.⁵⁸

Recombinant Subunit Vaccines. DENV vaccines composed of recombinant E proteins also have been studied. Analogous to DNA vaccines, this approach may simplify the task of eliciting a balance tetravalent response.²¹⁷ High-level expression of soluble forms of the E protein has been achieved using insect cell gene expression technologies. Whether the antigens in subunit vaccines are capable of eliciting the full spectrum of antibody specificities required for a maximally protective response, particularly those spanning multiple E protein oligomers on the intact virion, remains uncertain.

Other/Modified Viral Vectors. Several viral expression vectors have been studied in mice and primates as possible DENV vaccine platforms including vaccinia virus,^{97,195} alphavirus,^{143,881} adenovirus,⁶⁷³ and measles virus.⁹²

Japanese Encephalitis Virus

JEV is a principal cause of pediatric encephalitis in Asia and has been a focus of vaccine development efforts since before World War II.³⁰² Inactivated suspensions of JEV-infected mouse brains were administered to military personnel in response to an outbreak of Japanese B virus (now recognized as JEV) on Okinawa in 1945.⁶⁹⁹ Although circumstances did not permit a complete evaluation of efficacy, this vaccine elicited neutralizing antibodies in a subset of vaccinated subjects at titers that protected mice from lethal infection.⁶⁹⁸ Since that time, considerable progress has been made toward developing a safe and effective JEV vaccine. Three vaccination approaches have reduced the incidence of JEV in countries with the means to utilize them. However, ~35,000 to 50,000 cases of JEV disease annually are still seen; as such, efforts to develop effective and economical vaccines with improved safety profiles continue.⁵³

MOUSE-BRAIN DERIVED JEV VACCINES

Vaccines produced from JEV-infected mouse brains have been effective at controlling JEV in many parts of Asia, including Japan, South Korea, Taiwan, and Thailand.²³⁵ The Research Foundation for Microbial Diseases of Osaka University (BIKEN) produced the majority of mouse-brain derived JEV vaccine licensed for international use between 1954 and 2005. This vaccine platform uses genotype III Nakayama or Beijing-1 strains for different markets.⁵³ Brain tissue from intracranially infected mice is homogenized, and virus is purified by ultracentrifugation and filtration steps. The materials are inactivated by formalin during this process.³³⁵ These vaccines were used primarily in Japan, Korea, Thailand, Malaysia, Sri Lanka, and Vietnam to protect against endemic JEV.⁵³ The BIKEN vaccine was licensed for travelers in the United States and elsewhere and marketed as JE-VAX™.²³⁵

Efficacy studies of mouse brain-derived JEV vaccines suggest that they are modestly immunogenic, and thus require multiple boosts. A placebo-controlled double-blind evaluation of monovalent (Nakayama strain) or bivalent (Nakayama and Beijing strains) formulations of JE-VAX conducted in Thailand revealed an efficacy of 91% in children receiving two doses of vaccine 7 days apart.³³⁵ However, interpretation of these studies is complicated by the prevalence of individuals with prior flavivirus experience in JEV-endemic regions. Studies of the

immunogenicity of two doses of JE-VAX in flavivirus-naïve subjects revealed only 33% seroconversion at 26 weeks postvaccination; in subsequent studies, near complete seroconversion was achieved using a third dose.^{657,707} Attempts to measure the durability of antibody responses elicited by mouse brain-derived vaccine in endemic regions have been complicated by the potential boosting by naturally acquired flavivirus infection. Studies of military vaccine recipients suggest that neutralizing antibodies may persist for at least 3 years.²⁴⁴ Vaccine is typically administered in two doses separated by 1 to 4 weeks, followed by a booster 1 to 2 years later. Travelers require a rapid three-dose vaccination regimen (days 0, 7, and 30).²³⁵

Although mouse brain-derived JEV vaccines have shown efficacy in humans, they are reactogenic and raise concerns about vaccine safety. Roughly 20% of JE-VAX recipients experience local adverse events including swelling, redness, and tenderness at the vaccination site, and mild systemic symptoms are also relatively common. Severe allergic and neurologic (acute disseminated encephalomyelitis [ADEM]) complications of vaccination have been observed (10 to 260 and 0.1 to 2 per 100,000 vaccinees, respectively).^{53,235} Fatalities from ADEM resulted in cessation of production of JE-VAX in 2005 in favor of newer vaccines with more favorable safety profiles.

LIVE ATTENUATED JEV VACCINES

SA14-14-2 is a live-attenuated JEV vaccine that has been administered to more than 300 million individuals.³⁰² The parental SA14 strain was isolated from the larvae of *Culex pipiens* mosquitoes collected in China in 1954, and causes lethal neurologic disease when inoculated into weanling mice via the intracranial route. The attenuated strain was developed after extensive passaging of the SA14 strain in cell culture, and in hamsters and suckling mice.^{613,898} The SA12-1-7 strain was isolated by passage of SA14 in newborn mice 10 times and 100 passages in primary hamster kidney cells.⁶¹⁴ Although this virus was considerably less virulent than SA14, it was not genetically stable and reverted to a neurovirulent phenotype following a single passage in mice, or several passages in primary cell cultures.⁹⁰⁸ Derivatives of this virus with greater genetic stability were subsequently developed and evaluated. SA14-5-3 was derived from SA12-1-7 by additional passages in cell culture and plaque purification steps. Clinical studies demonstrated vaccine safety in humans but only modest immunogenicity, with seroconversion rates of 85% and 61% in endemic and nonendemic regions, respectively.³⁰² SA14-5-3 was licensed for use in China; altogether about 5 million children were vaccinated.⁹⁰⁸ To improve immunogenicity, additional passages of SA14-5-2 in suckling mice yielded the SA14-14-2 strain. A single dose of SA14-14-2 induced a neutralizing antibody response in 85 to 100% of non-immune recipients.^{767,833,898} Case-controlled studies demonstrated that a single dose of SA14-14-2 vaccine provided considerable protection (80% to 99%),^{76,327,431,626} which was durable even after 5 years.⁸⁰⁹ SA-14-14-2 was licensed for use in China in 1988, and subsequently distributed in Nepal, South Korea, Sri Lanka, Thailand, and India.

INACTIVATED JEV VACCINES PRODUCED IN CELL CULTURE

The IC51 (or IXIARO) vaccine is a formalin-inactivated vaccine produced in certified Vero cells under serum free conditions and adjuvanted with aluminum hydroxide.²³⁵ IC51 uses the SA14-14-2 JEV strain,⁴¹⁴ and is administered in two doses

28 days apart, each containing ~6 µg of purified virus. Licensure was granted based on a noninferiority immunogenicity study comparing the response of recipients receiving IC51 to those vaccinated with a three-dose regimen of JE-VAX. Although a single dose of IC51 was poorly immunogenic (41% seroconversion), 4 weeks after the last of three doses, 96% of recipients had detectable neutralizing antibodies, and these persisted in most subjects 6 months after vaccination.⁴¹⁴ No significant local or systemic adverse events were associated with vaccination; rare events await a more detailed analysis of larger populations of vaccine recipients. IC51 was licensed for use in the United States as a traveler's vaccine in 2009 for individuals older than 17 years of age. An inactivated JEV vaccine derived from the genotype III P3 strain and produced in hamster cell cultures also has been used extensively in China, with as many as 70 million doses of this vaccine administered each year.³⁰²

NEW VACCINATION APPROACHES

ChimeriVax-JE, or IMOJEV, is a promising live attenuated vaccine constructed using the attenuated YF17D backbone described above (reviewed by⁵⁵). ChimeriVax-JE was constructed by inserting the prM-E genes of YF-17D, with genes encoding the envelope proteins of SA-14-14-2. Vaccination with ChimeriVax-JE elicits a protective response in mice and primate studies.^{55,288,576} Clinical studies in humans reveal the vaccine is well tolerated and immunogenic (reviewed by²⁹²).

Tick-Borne Encephalitis Virus

Two inactivated TBEV vaccines are used to prevent infection in Europe, but are not licensed in the United States.⁶⁷⁷ Kunz and colleagues^{436,437} developed the first licensed vaccine in 1973 using the Austrian Neudörfl strain of TBEV grown in chick embryo fibroblasts, after inactivation with formalin and adjuvanting with aluminum hydroxide. Today, this vaccine is distributed as FSME-IMMUN by Baxter Biosciences. A second vaccine, produced by Novartis and marketed as Encepur,^{83,407} was licensed in 1991. It is produced using similar methods, except the German K23 strain of TBEV is substituted. Both inactivated TBEV vaccines are administered in three doses and require boosting. The conventional schedule requires three vaccinations at 0, 1–3 months, and 9–12 months, and a booster at 3 years, followed by additional booster vaccinations every 5 years. These vaccines are highly immunogenic; virtually 100% of vaccinated subjects develop significant neutralizing antibody titers following their third dose,⁴³⁶ and antibodies persist for at least 5 years.^{652,887} The effectiveness of current TBEV vaccines in the field has been estimated at about 99%.³²⁰ Despite the availability of effective vaccine, TBEV incidence in parts of Europe recently has increased, coincident with poor vaccine coverage.⁴³⁸

West Nile Virus

Several strategies for vaccination against WNV have been developed and evaluated in clinical studies (reviewed in⁵¹). Live-attenuated flavivirus chimeras have been developed for WNV using the strategies described above for DENV and JEV. ChimeriVax WNV was constructed by replacing the genes encoding the prM-E proteins of YF-17D with those of WNV.²⁹² Two vaccines were developed using this approach. ChimeriVax-WN01 encodes the unmodified sequence of the NY99 strain, and was developed as a veterinary vaccine that has been in use in horses since roughly 2006.^{498,499} ChimeriVax-

WN02 differs from the veterinary vaccine by three amino acid substitutions in the E protein introduced to reduce neurovirulence, and a fourth adventitious substitution that arose during adaptation of the vaccine lot to growth on Vero cells.²⁹² ChimeriVax-WN02 has been shown to be safe and immunogenic in phase I and phase II clinical trials in humans.^{72,574} Chimeric flavivirus vaccine candidates have also been constructed using the DENV4Δ30 backbone described earlier (see DENV section) and have proven to be safe and immunogenic in preclinical⁶⁰⁶ and clinical studies (A. Durbin, S. Whitehead, and colleagues, unpublished data; ClinicalTrials.gov identifier: NCT00094718).

Despite their effectiveness, concerns about the potential hazards associated with the use of live-attenuated viral vaccines provide a strong rationale for the development of other approaches. DNA vaccination has also shown promise for WNV vaccination. DNA vaccine constructs typically express genes encoding the prM and E structural proteins. Expression of prM-E *in vitro* is sufficient for the production of small virus-like subviral particles on which the E proteins are arrayed with icosahedral symmetry²³³; DNA vaccines are thought to produce subviral particles upon administration *in vivo*. Two phase I clinical studies of a WNV nucleic acid vaccine have been performed.^{180,453,530} These trials demonstrated that three doses of vaccine were well-tolerated and capable of eliciting both a T-cell and neutralizing antibody response. A similar construct has proven to be efficacious at reducing WNV incidence in horses and a variety of birds.⁵¹

An adjuvanted subunit vaccine containing a soluble fragment of the WNV E protein has been developed^{473,474,873} and studied in humans (ClinicalTrials.gov identifier: NCT00707642). A truncated form of the E protein lacking the transmembrane domains (referred to as 80% E) was produced in *Drosophila* S2 cells and purified using immunoaffinity chromatography. Preclinical studies demonstrate that administration of a single dose of adjuvanted protein was immunogenic and capable of eliciting a neutralizing antibody response.^{473,474,873} To date, the results of a phase I clinical study of this vaccine have not been published.

Replivax-WN is a truncated form of the WNV genome encoding a large deletion in the gene encoding the capsid protein. This construct can be complemented *in vitro* using cell lines that express the capsid protein to yield pseudoinfectious virus particles. Infection of cells with these virus particles is not productive, yet it results in the production of subviral particles composed of prM and E. Immunization with Replivax particles has been shown to be safe in preclinical studies and stimulates a robust adaptive response.^{606,884,885} A similar modification of the Kunjin virus genome has been evaluated as a candidate WNV vaccine.¹³³

Altogether four veterinary vaccines have been licensed for use including a formalin-inactivated adjuvanted whole virus vaccine (WN-Innovator, Fort Dodge Animal Health), a canarypox vector expressing prM and E (Recombitek equine WNV vaccine),^{219,378,760} ChimeriVax-WN01 (PreveNile),²⁹² and a DNA vaccine construct that served as the basis for the human vaccine described above (WN-Innovator DNA, Fort Dodge Animal Health).¹⁸⁰

Therapeutics

At present, no specific therapy has been approved for use in humans with any flavivirus infection, as all current treatments

are supportive. For example, treatment of severe DHF/DSS currently consists of careful patient monitoring and aggressive fluid management. Although tissue culture and animal model studies have applied multiple screening strategies to generate novel therapies against flaviviruses, development has remained challenging. Among the impediments are the rapid development of resistance for monotherapy, a need to efficiently cross the BBB for inhibitors of the encephalitic flaviviruses, and regulatory hurdles for the design and implementation of multicenter trials, given the sporadic temporal and spatial occurrence of many flavivirus infections.

Existing Antiviral Agents: Ribavirin, Mycophenolic Acid and Human IFN- α

Ribavirin is a broad-spectrum antiviral agent and has been used clinically to treat respiratory syncytial, hepatitis C, Lassa fever, and Crimean-Congo hemorrhagic fever viruses. It acts as a guanosine analog and competitively inhibits inosine monophosphate dehydrogenase (IMP), resulting in depleted intracellular guanosine pools.⁴⁶² This activity has been proposed to interfere with the guanylation step of RNA capping, inhibit viral polymerases, or compromise the integrity of the viral genome by being incorporated directly into the nascent RNA strand and serving as a template for both cytidine and uridine.^{172,173,184} Ribavirin has inhibitory activity against flaviviruses infection in cell culture,^{166,365,807} albeit at relatively high micromolar concentrations. Limited animal studies have been performed with varying results. Although a beneficial therapeutic effect of ribavirin was observed in YFV-infected hamsters,^{366,715} treatment of YFV-infected NHP had minimal positive effect,⁵⁶⁴ and increased mortality was observed in WNV-infected hamsters.⁵⁸⁰ A combination of ribavirin with IFN- α_{2b} also failed to improve outcome of flavivirus-induced encephalitis in mice.⁴⁶³ Finally, during a WNV outbreak in Israel in 2000, in an uncontrolled study, 37 patients received ribavirin and had a higher mortality rate.¹⁵¹

Mycophenolic acid (MPA) is a nonnucleoside inhibitor of IMP dehydrogenase that is used clinically to prevent rejection of transplanted organs. The immunosuppressive properties of MPA are attributed to its antiproliferative effect on lymphocytes *in vitro*. MPA inhibits to varying degrees the replication of a number of DNA, RNA, and retroviruses. Several studies have demonstrated that MPA inhibits flavivirus infection in cells by limiting viral RNA replication.^{206,585,807} Although MPA blocks flavivirus infection in cell culture, its immunosuppressive properties *in vivo* likely overshadow its direct antiviral effects, as no study has reported therapeutic benefit in animals.

Type I IFN induces an antiviral state within cells through the induction of antiviral proteins and by modulating adaptive immune responses. Despite the ability of flaviviruses to antagonize its signaling pathways, pretreatment of cells with type I IFN potently inhibits infection by many flaviviruses. Nonetheless, IFN may still have therapeutic potential. Pretreatment of rodents with IFN- α inhibited SLEV infection and resulted in decreased WNV viral loads and mortality.^{106,580} Analogously, treatment of before or after YFV infection also improved survival rates.³⁶⁶ Administration of IFN- α reduced complications in human SLEV cases and has been used in an uncontrolled manner to treat small numbers of human cases of WNV encephalitis.^{374,461,670} However, in Vietnam, a double-blinded, randomized placebo-controlled clinical trial was performed in

1,112 children with suspected or documented encephalitis virus infection; treatment with IFN- α_{2a} failed to improve outcome.⁷⁷⁰

Passive Antibody Therapy

Through experiments in a variety of experimental systems, it is well established that antibodies can neutralize flavivirus infection *in vitro* and *in vivo*, and prophylaxis or immunization can provide sterilizing immunity and prevent infection. The ability to cure animals with established flavivirus infection by passive transfer of antibodies, however, is more challenging and depends on the dosage, time of administration, and individual flavivirus.⁶⁹¹ For some flaviviruses, there are concerns that treatment could promote ADE and paradoxically exacerbate disease. In both monkeys and mice, subneutralizing concentrations of antibody enhanced DENV infectivity^{39,265,309,912} and thus could complicate the antibody therapy. Apart from or perhaps related to ADE, an “early-death” phenomenon⁵⁷⁹ has been reported that could also limit the utility of antibody therapy. According to this model, animals that have preexisting humoral immunity but do not respond well to viral challenge may succumb to infection more rapidly than animals without preexisting immunity. Although it has been described after passive acquisition of antibodies against YFV and Langat encephalitis viruses,^{43,269,875} this phenomenon was not observed after transfer of monoclonal or polyclonal antibodies against WNV,^{64,225,627} JEV,³⁹⁶ or TBEV.⁴²³

Although preexposure passive transfer of neutralizing antibodies protects successfully against infection by many flaviviruses,^{199,691} postexposure therapeutic studies have been performed in a more limited fashion, primarily with antibodies against WNV, TBEV, and DENV. In therapeutic trials, immune human γ -globulin protected mice and hamsters against WNV-induced mortality.^{62,64,225,367} Therapeutic intervention even 5 days after WNV infection reduced mortality; this time point is significant because in rodents WNV spreads to the brain and spinal cord by day 4. Therefore, passive transfer of immune antibody improved clinical outcome even after WNV had disseminated into the CNS. Analogously, postexposure treatment with polyclonal immune immunoglobulin decreased TBEV lethality in mice, with the degree of protection correlating with the amount of antibody administered and the time interval between infection and treatment.⁴²³

Humans have received passive therapy with immune γ -globulin against flavivirus infection. The largest experience is with commercial anti-TBEV antibody preparations (Encegam® and FSME-Bulin®). These products were available beginning in the 1970s, and recommended for treatment within a few days of a tick bite at risk for TBEV infection,¹⁰⁵ with between 70,000 and 200,000 doses administered.¹⁸ However, worsened illness after treatment was reported in three children,^{410,854} although no definitive clinical trial was ever conducted. Subsequently, immune γ -globulin production was suspended in the European Union, and Latvia remains the only European country where TBEV-specific immunoglobulin is still given.¹⁰⁵ In comparison, case reports have described improvement in humans with neuroinvasive WNV infection after receiving immune γ -globulin.^{295,745} Although promising, γ -globulin immunotherapy against WNV infection in humans has limitations: (a) batch variability may affect the quantitative titer and functional activity; (b) it is purified from human plasma and has a theoretical risk of transmitting infectious agents; and (c) it requires a large

volume of administration, which can increase adverse events in patients with cardiac or renal comorbidities.

More recently, humanized or human monoclonal antibodies or antibody derivatives with therapeutic activity against WNV infection^{272,627,823,850} have been developed. These human or humanized antibody fragments have high neutralizing activity *in vitro* and provide excellent protection in rodents. When some humanized mAbs were given as a single dose 5 or 6 days after infection, 90% of mice or hamsters were protected.^{581,627} Acute flaccid paralysis in hamsters also was blocked by treatment several days after infection using one anti-WNV neutralizing antibody.⁷⁰⁵ A phase II randomized, double-blinded clinical trial to evaluate safety and efficacy of this humanized antibody (E16, also termed MGAWN1) against severe WNV infection was recently completed (ClinicalTrials.gov identifier: NCT00515385). Neutralizing antibody therapeutics show promise, as they directly inhibit transneuronal spread of WNV infection and prevent the development of paralysis *in vivo*. Future use of a combination of monoclonal antibodies that bind distinct epitopes and neutralize by independent mechanisms could diminish the potential risk of selecting escape variants *in vivo*, especially in immunocompromised individuals who generate high-grade viremia and tissue viral burden.

Antibody-based therapeutics more recently have been proposed as a possible treatment for DENV infection. Although somewhat counterintuitive, because of the theoretical risk of ADE and immune-enhanced disease *in vivo*, genetically engineered antibody variants (E60-N297Q, 82.11-LALA, and 87.11-LALA) that recognize conserved epitopes in domain II or domain III and cannot bind Fc γ R exhibited prophylactic and therapeutic efficacy against ADE-induced lethal challenge of DENV-2 in mice.^{39,61} These observations suggest a novel strategy for the design of antibody-based therapeutics against DENV.

Nucleic Acid Inhibitors

RNA Interference

RNA interference (RNAi) is a cellular process that specifically degrades RNA within the cytoplasm of cells in a sequence-specific manner. RNAi occurs in plants, nematodes, parasites, insects, and mammalian cells and functions as a regulator of cellular gene expression and an innate defense against RNA viruses. RNAi uses dsRNA to target and degrade sequence-specific single-stranded RNA (ssRNA). The cytoplasmic ribonuclease Dicer recognizes and cleaves long dsRNA molecules into approximately 21 to 25 base pair small interfering RNA (siRNA) molecules; these associate with the RNA-induced silencing complex (RISC) to target and degrade complementary ssRNA molecules.⁷⁷³ The viral targets of RNAi have included double-stranded replicative-intermediate RNA or highly structured hairpin regions in single-stranded viral genomic RNA. In addition, any single-stranded viral RNA may be targeted and converted first to dsRNA by a cellular RNA-dependent RNA polymerase before recognition by Dicer.⁹

Many mammalian viruses appear susceptible to treatment with exogenous siRNA. Cells that express virus-specific siRNA or shRNA are resistant to infection by WNV,^{15,249,631,900} DENV,⁷⁹³ YFV,⁶³⁴ SLEV,⁹⁰⁴ and JEV.⁴²⁹ The sequence-specific activity of siRNA against viruses has led to great interest in its potential as antiviral therapy. Administration of siRNA to mice reduces flavivirus infection and affords partial protection against lethal challenge.^{32,429,634,904} WNV-specific siRNA could

act efficiently as a therapeutic after viral challenge, although administration within 6 hours of infection was required.⁴²⁹ No significant protection was observed when siRNA was delivered 24 hours after infection.³² Although promising, RNAi-based therapeutics against viruses may await the development of delivery systems that allow more effective activity against actively replicating viruses.

Antisense Technology

Antisense oligomers have been used to modulate gene expression of pathogenic viruses, and several are in various stages of clinical development.⁵¹¹ These compounds inhibit flaviviruses by binding RNA in a sequence-specific manner, effectively blocking access to a particular region of the viral genome. The development of phosphorodiamidate morpholino oligomers (PMOs) has enhanced water solubility and nuclease resistance,⁷⁹⁶ and the conjugation of arginine-rich peptides to PMOs has facilitated cellular uptake and inhibitory activity.⁶⁰⁹ Sequence-specific antisense oligomers have inhibitory activity in cell culture against several flaviviruses, including WNV^{189,190} and DENV.^{336,401} Low micromolar concentrations of arginine-rich peptide-conjugated PMOs that target the 5' untranslated or 3' cyclization sequences inhibited flavivirus infection by 5 to 6 log₁₀ PFU/ml^{190,401} when administered as pretreatment. However, when given either 2 or 4 days after infection, peptide-conjugated PMOs had little or no antiviral effect. PMO directed against the 5' and 3' conserved sequences partially protected mice from WNV or DENV infection and disease without causing appreciable toxicity,^{189,782} although selection of resistant mutants was observed.¹⁸⁹ Some clinical improvement was observed when PPO was administered to mice at day 5 after infection, although statistically significant differences were not achieved. AVI Biopharma initiated a phase I human clinical trial for treatment of WNV infection (ClinicalTrials.gov identifier: NCT00091845) with AVI-4020, but the study was terminated prematurely due to a limited pool of eligible subjects.

Flavivirus Antiviral Peptides

FuzeonTM is a peptide-based fusion inhibitor approved for clinical use in HIV-infected patients. Although structurally distinct, the flavivirus E proteins undergo an analogous series of pH-dependent conformational changes that permit entry, fusion, and nucleocapsid escape into the cytoplasm (see section on Virus Entry and Tropism). Exogenous administration of peptides corresponding to prM protein⁹¹⁹ or the stem anchor domains^{342,727,728} of WNV and DENV E proteins inhibit infectivity in cell culture, likely during a late stage of the fusion process. Peptides corresponding to sites in domain II and the domain I–II hinge interface also inhibited DENV infection in cell culture at the level of virus–cell attachment.¹⁶³ Finally, another group identified two E protein peptides that could inhibit WNV infection with half maximal effective concentration (EC₅₀) values as low as about 3 mM. Mice challenged with WNV that had been administered these inhibitory peptides showed reduced viremia and lethality.³¹ Although this is an emerging area of therapeutic development for flaviviruses with multiple possible targets, clinical studies have not yet been initiated.

Iminosugars

In flavivirus-infected mammalian cells, a 14-residue oligosaccharide (Glc)₃(Man)₉(GlcNAc)₂ is added in the ER to specific

asparagine residues on the prM and E virion proteins. This high-mannose carbohydrate is sequentially modified in the ER and Golgi by resident glucosidases to generate N-linked glycans that lack the terminal $\alpha(1,2)$ and $\alpha(1,3)$ glucose residues. Trimming of N-linked glycans in the ER is required for efficient assembly and secretion of flaviviruses in mammalian cells.^{164,892} Iminosugar derivatives, such as deoxynojirimycin or castanospermine, inhibit endoplasmic reticulum α -glucosidases I and II. This prevents processing of high-mannose N-linked glycans from nascent glycoproteins, a step that is required for interaction with the ER chaperones, calnexin, and calreticulin. Several flaviviruses are strongly inhibited by α -glucosidase inhibitors *in vitro*^{135,164,281,737,880,892} and *in vivo*.^{134,880} One possible advantage of α -glucosidase inhibitors is that they target a host enzyme that is an essential step in virus secretion rather than the virus directly, and are thus less likely to select for resistant variants.

High-Throughput Screens with Small Molecule Inhibitors

Over the last decade, high-throughput screens (HTS) with small molecule libraries have identified classes of “druggable” compounds that inhibit flavivirus infection. Several strategies have been utilized in high-throughput platforms including approaches that target viral enzymes, host proteins, key viral protein structures, and viral replication.⁶²⁰ HTS screens that directly or indirectly assess flavivirus replication have measured inhibition of cytopathic effect of viral infection, reporter gene expression in the context of a flavivirus replicon, or viral antigen expression by immunofluorescence and automated microscopy.^{282,622,659,660} Among viral targets, inhibitors that attenuate NS2B-NS3 protease activity, NS5 methyltransferase activity, and NS5 RNA-dependent RNA polymerase activity of different flaviviruses have been identified. Possible host targets for HTS include furin-like enzymes or signal peptidases that promote virion maturation, c-Src and c-Yes kinases that are required for assembly and maturation, cholesterol and lipid biosynthesis, and immune response genes. High-resolution x-ray crystal structures of key viral proteins (e.g., C, prM, E, NS3, and NS5) have informed structure-based design and *in silico* screening of inhibitors to augment the potency of lead antiviral compounds. Co-crystallization of lead candidate inhibitors with protein targets can determine the topology and consequences of binding, so that structure-activity related variants with augmented efficacy can be designed.

More limited studies have been performed with small molecule inhibitors in animals to assess therapeutic potential. One oral pyrazine derivative with broad-spectrum antiviral activity, T-705 (6-fluoro-3-hydroxy-2-pyrazinecarboxamide) was protective in rodents when administered twice daily beginning 2 days after WNV infection.⁵⁸⁶ However, administration of T-705 at days 3 or 4 after infection showed little apparent efficacy. A small molecule nucleoside analog (e.g., NITD203) that targets flavivirus RNA synthesis showed efficacy against DENV in mouse models,¹⁴⁸ although its significance as a possible therapeutic agent appears limited by *in vivo* toxicity.

Given their continued global emergence and expansion, the development of antiviral agents against flaviviruses as a complement to intensive vaccine design strategies is essential. At present, several candidate therapies that act through distinct mechanisms are moving through various stages of preclinical and clinical development. Based on the pathogenesis of infection by different

flaviviruses, therapeutic agents may pair potent and direct antivirals with drugs that mitigate immune system-mediated inflammation and damage. For the encephalitic flaviviruses, inhibitors may need to cross the BBB efficiently to allow for control of local replication within neurons. For some flaviviruses where disease is sporadic and less predictable on an annual basis, regulatory hurdles will be encountered in implementing multicenter trials. Because of this, extensive preclinical experiments in small animals and NHPs may be useful to define whether a candidate therapeutic should reach human clinical trials. Ongoing pathogenesis and infection studies will inform novel drug design strategies that target individual viral proteins. Experiments in animals should continue to define the essential components of the protective immune response, and the immunologic risk factors that predispose to severe neurologic disease. Ultimately, a combination drug strategy that blocks viral infection, minimizes tissue injury, and limits the development of resistant variants will likely be more effective than single agents.

ACKNOWLEDGMENTS

We thank Mr. Ethan Tyler (OD, NIH) for preparation Figures 2, 6 to 8, 10, and 11; Dr. Richard Kuhn (Purdue University) for preparation of Figures 4 and 5; and Dr. Jiraphan Junjhon (Purdue University) for providing the unpublished image of DENV used in Figure 26.4C.

HISTORY

By the mid-1970s, it was apparent that at least one viral hepatitis agent other than hepatitis A virus (HAV) or hepatitis B virus (HBV) was the primary agent of posttransfusion hepatitis, a syndrome termed “non-A, non-B” hepatitis (NANBH).^{197,335} Studies of transfusion recipients revealed that NANBH tended to be milder in its acute form than HBV but could cause severe complications including cirrhosis and liver failure.¹⁶ Inoculation of chimpanzees with blood components from humans having both acute and chronic NANBH resulted in characteristic elevations of hepatic transaminases, providing a valuable animal model for NANBH and establishing the chronic nature of NANBH.¹⁷ By the mid-1980s, physicochemical studies of infectious inocula had revealed that the NANBH agent was a small (less than 80 nm), enveloped virus; however, the agent defied efforts directed at conventional viral cultivation and immunological detection.^{76,159}

Serial passage of NANBH in chimpanzees provided key pathologic, physiologic, and biochemical insights, as well as a well-characterized pool of specimens in which the agent was known to be present. A team led by Michael Houghton assembled a lambda phage library of complementary DNA (cDNA) derived from one such high-titer chimpanzee plasma specimen and then screened more than 1 million expression clones using serum from a chronic NANBH patient to find a single positive cDNA clone called 5-1-1.¹¹⁶ This discovery led to initial assays for detection of antibodies to the newly named hepatitis C virus (HCV),^{18,116,352} and the 5-1-1 antigen continues to be a component of anti-HCV serologic tests.

The first cDNA clone enabled further characterization of the genome as a positive-strand RNA molecule of almost 10,000 nucleotides containing a single open reading frame with an organization consistent with the *Flaviviridae*.¹¹⁷ Discovery of the authentic 5′ and 3′ untranslated regions (UTRs) led to a full-length cDNA clone of the HCV genome that, when transcribed, was infectious by direct intrahepatic injection in chimpanzees.³³⁷ The development of *in vitro* model systems was relatively intractable until the development of subgenomic RNA replicons³⁸⁷ and then successful passage in cell culture of a clone from one strain.⁶⁷⁰

HCV continues to present unresolved scientific and clinical challenges. Questions persist regarding fundamental aspects of the HCV life cycle, replication dynamics *in vivo*, mechanisms of persistence, and pathogenesis. Screening of blood products using antibody- and then nucleic acid–based testing, combined with other blood banking practices, provides a sound basis for the virtual elimination of transfusion-transmitted HCV infection; nonetheless, new infections continue to occur via other routes. Nearly 3% of humans remain chronically infected with

HCV, and although treatment continues to improve in efficacy and availability, HCV infection remains a major cause of death and disability worldwide.

PATHOGENESIS AND PATHOLOGY

Entry into the Host

As discussed in the Transmission section later (under Epidemiology), the primary route of HCV entry is percutaneous, although permucosal infection has also been described. Experimentally, HCV infection can be achieved by intravenous injection of HCV virions or intrahepatic injection of HCV genomic RNA.^{337,694}

Cell and Tissue Tropism

As depicted in Figure 27.1, HCV replication *in vivo* occurs primarily or exclusively in hepatocytes, the major parenchymal cell of the liver.⁵⁰⁵ The basis for this tropism is likely to be multifactorial, including entry facilitated by proteins expressed at particularly high levels on hepatocytes (e.g., low-density lipoprotein receptor [LDL-R]⁴⁴⁶ and scavenger receptor class B type I [SR-BI]^{185,248,557}), dependence on liver-specific miR-122 for efficient replication,²⁹⁹ and utilization of the liver's lipoprotein assembly pathway for virion production.²⁸⁰ Tissue-specific subcellular localization and dynamic interaction between viral components and more broadly expressed proteins on which HCV replication depends (such as CD81,^{195,248,270,320,499} claudins [CLDNs],^{183,267,270,422} occludin [OCLN],⁵⁰⁰ epidermal growth factor receptor,³⁹² and cyclophilins²⁵⁷) may also contrib-

ute to liver-specific tropism. HCV entry is discussed in detail in Chapter 25.

Extrahepatic Replication

Productive infection of other cell types is controversial,^{70,362} but there is evidence for extrahepatic detection of HCV negative-strand replicative intermediates,^{106,375,701} sequence variant compartmentalization,^{459,562} and *in vitro* replication in a variety of cell types.^{602,608} Viral dynamic modeling of data from the anhepatic phase of liver transplantation suggested that in a subset of patients with end-stage liver disease, an extrahepatic compartment exists that contributes no more than 3% to 4% of plasma viremia.^{142,505}

Model Systems *In Vitro*

During the first decade after HCV was discovered, the only robust model was the chimpanzee infected with primary or chimpanzee-passaged HCV isolates. Efforts to culture HCV from human and chimpanzee serum using primary hepatocytes or hepatoma cell lines were limited by relatively insensitive tools for measuring and visualizing infection, inconsistent cell lines, and the inherent variability of HCV isolates (see Genetic Diversity, later).^{284,290,313,444,445,454,570,697} Without an efficient culture system, screening of candidate antivirals was hampered.

The First Infectious Clone

In 1997, two groups separately reported chimpanzee infection with infectious clones of HCV,^{337,694} generated from acute phase isolate H77¹⁷ by using overlapping sequences spanning the genome (Fig. 27.2) to identify low-frequency polymorphisms

FIGURE 27.1. Life cycle of hepatitis C virus (HCV). Initial binding and internalization (1) probably involve glycosaminoglycans (GAGs) and low-density lipoprotein receptor (LDL-R), which may interact with viral envelope proteins or with virion-associated lipoproteins. Entry depends directly on binding of E2 with the tetraspanin CD81, as well as interactions with scavenger receptor BI (SR-BI) and tight junction proteins claudin-1 and occludin (OCLN). The viral genome is released from late endosomes (2) in a pH-dependent manner, followed by internal ribosome entry site (IRES)-dependent polyprotein synthesis (3) with initial cleavages among the structural proteins mediated by signalase and signal peptide peptidase followed by cleavage of the NS2–NS3 junction by NS2–NS3 cysteine protease; the remaining junctions are cleaved by the NS3–NS4A serine protease. NS4B recruits and rearranges endoplasmic reticulum (ER) membranes (4) to form a *membranous web*, the principal site of viral replication. Minus-strand and subsequent plus-strand RNA syntheses are affected by the NS5B RNA-dependent RNA polymerase (RdRp) (5) and depend on miR-122 and cyclophilin B, as well as conserved structural elements at the 5' and 3' ends of the genome. Core protein associates with lipid droplets (LDs) in the lipoprotein assembly pathway (6), linked to NS5A and other members of the replication complex by interaction with NS2. Viroporin p7 is necessary for production of stable viral particles coated with E1 and E2, which fold in a cooperative manner and are glycosylated in a manner consistent with ER but not Golgi processing.

FIGURE 27.2. Map of the hepatitis C virus (HCV) genome, depicting the 5' untranslated region (5'UTR), capsid core, envelope genes *E1* and *E2*, viroporin *p7*, membrane-anchored cysteine protease *NS2*, serine protease-helicase *NS3*, *NS3* protease co-factor *NS4A*, membrane remodeling protein *NS4B*, phosphoprotein *NS5A*, RNA-dependent RNA polymerase *NS5B*, and the 3'UTR. Depicted as green bars are protein segments used as antigens in HCV enzyme immune assay (EIA) and recombinant immunoblot assay (RIBA) (c22, c33, c100-3⁵²). Cleavages of the polyprotein are due to the action of signal peptidase (solid orange), signal peptide peptidase (open orange), *NS2* cysteine autoprotease (green), and *NS3-NS4A* serine protease (blue).

that were likely to be either artifactual (generated during cDNA cloning) or biologically genuine but less infectious. By removing such minor sequence variations, they constructed consensus sequences that were infectious, paving the way for the generation of consensus sequences from other isolates in search of clones that would replicate efficiently *in vitro*.⁵¹

HCV Replicons

In 1999, the efficient replication of subgenomic replicons in hepatoma cell line Huh-7 was reported, representing the first culture system that depended on HCV enzymes for propagation of a selectable marker (driven in a 2-internal ribosome entry site [IRES] bicistronic construct) and permitting more direct study of the viral life cycle.³⁸⁷ Highly replicative subtype subgenomic replicons were developed and were shown to depend on intact viral enzymatic sequences and negative-strand subgenome intermediates, inhibited by interferon- α .^{64,386} This latter characteristic opened the door to “curing” of cultures with interferon, resulting in Huh-7–derived cell lines like Huh-7.5⁶⁵ that were more permissive for HCV replication, an important tool for subsequent achievements including authentic culture of HCV *in vitro*.

Although cell culture adaptation of replicons permitted greater dynamic range of replication sufficient for screening inhibitors and studying viral protein interactions, the adaptive changes^{64,343,386} were often found to impair infectivity *in vivo*,⁸⁵ and when they included the structural and *p7* genes, these replicons did not produce structural proteins or viral RNA in the supernatant. Strains that were assembled from human isolates as consensus clones but required no adaptive changes as replicons were identified, including subtype 1b strain HCV-N, which was also infectious in chimpanzees,²⁸⁵ and subtype 2a strain JFH-1.^{315,316} When these were assembled as full-genome replicons, JFH-1 was found to produce infectious viral particles.

HCV Cell Culture

In 2005, the complete replication cycle of HCV in culture was described, using the subtype 2a strain JFH-1 in Huh-7–derived cells that had been made more permissive by eradication of HCV subgenomic replicon infection with interferon.^{670,706} Subsequently, the HCV cell culture (HCVcc) platform was broadened to include subtype 1a strain H77-S.⁶⁹⁶ As discussed in Chapter 25, this system and derivatives such as chimeric structural and non-structural regions²⁴⁸ and reporter constructs³²⁸ provide new avenues for investigation of HCV biology and immunity.

HCV Pseudoparticles

Prior to the advent of HCVcc, HCV pseudoparticles (HCVpp) were developed to study HCV entry, which was found to be similar to other members of the *Flaviviridae*, and CD81 was found to be necessary but not sufficient for E1E2-mediated entry.^{46,279} HCVpp expressing a variety of *E1E2* genes have facilitated study of cross-subtype and cross-genotype neutralization^{436,478} and have been used to demonstrate that neutralizing antibodies drive the rapid evolution of *E2* during acute HCV infection.^{170,382}

Virion Production without HCV Replication

There are many uses for high-titer stocks of HCV, but these can be difficult to generate and achievable titers are dependent on genomic characteristics (e.g., culture adaptive mutations) that may interfere with intended uses. A novel system for generating virions was recently developed to address these challenges, using cells conditioned by replication of a West Nile virus replicon.⁶³⁸ Because this system does not depend on HCV replication, it is potentially HCV sequence (i.e., genotype) independent.

Model Systems In Vivo

The initial model for HCV infection was the chimpanzee, essential to the discovery of this virus and to key experiments described herein (e.g., Transmission, Immune Response, and Genetic Diversity sections). The chimpanzee remains the only model for studying the full range of host–HCV interactions, from acute to chronic infection.⁸⁴ The availability and use of chimpanzees is very limited,²² and other models are available that are relevant to specific areas.

Mice with Implanted Ectopic Human Liver Grafts

The Trimera severe combined immunodeficiency (SCID) mouse model, in which liver fragments remain viable for weeks after ectopic implantation (e.g., under the kidney capsule), can be used for studying HCV infection. The level of replication is modest ($10^{4.8}$ IU/mL) but high enough for testing antiviral regimens.²⁸⁶ The liver tissue in this model does not maintain normal architecture.

Mice with Liver Injury and Human Hepatocyte Xenografts

SCID mice transgenic for urokinase plasminogen activator (uPA) driven by the albumin promoter develop severe neonatal liver injury that is rescued by infused hepatocytes that engraft and

occupy the space of the involuting liver.⁴³¹ Similarly, RAG^{-/-}/interleukin-2 receptor- γ -deficient (IL2R γ ^{-/-}) mice bred for fumaryl acetoacetate hydrolase deficiency (FAH^{-/-}) develop hepatic toxicity but can be rescued pharmacologically with NTBC (2-[2-nitro-4-trifluoromethylbenzoyl]-1,3-cyclohexanedione) or by transfer of the FAH gene. These FRG mice (FAH^{-/-}, RAG^{-/-}, IL2R γ ^{-/-}) will accept infusions of human hepatocytes after infection with a uPA-expressing adenovirus (presumably to proteolytically damage the liver stroma).³⁵ These mice can achieve physiologic levels of human albumin and lipoprotein levels, and after infection with HCV they can develop high levels of HCV RNA (10⁶ IU/mL) and maintain these levels for months. The mice are difficult to breed and remain immunodeficient, and hepatocyte engraftment is highly variable; however, they are a useful model for HCV replication and have enabled mechanistic study of phenomena such as HCV neutralization *in vivo*.⁴³⁴

Humanized Mouse

A different approach from those described earlier was the recent development of a genetically humanized mouse model of HCV infection that partially addresses host restriction factors that block HCV infection of mouse hepatocytes.¹⁶⁸ Using adenovirus gene delivery to induce expression of potential restriction factors for entry, CD81,⁴⁹⁹ SR-BI,⁵⁵⁷ CLDN-1,¹⁸³ and OCLN,⁵⁰⁰ they found that human CD81 and OCLN were required for entry in the mouse. Mouse SR-BI knockout and human SR-BI complementation confirmed the necessity of SR-BI for HCV entry and that mouse SR-BI could substitute for human SR-BI in HCV entry. The remaining host restrictions for HCV infection of mice are unknown, but the use of adenovirus gene delivery may have enhanced innate antiviral responses, and the stable expression of CD81 and OCLN in the mouse will facilitate further study. At present, the genetically humanized mouse model supports entry but not replication of HCV.

Spread

The mode of spread of HCV throughout the liver is poorly understood. High-level viremia achieved by HCV provides ample opportunity for virions to interact with hepatocytes, yet it appears that only about 10% to 20% of hepatocytes are infected during chronic infection.³⁷⁸ Lack of uniform infection may be explained by innate responses that could render cells refractory and adaptive immunity that could interfere with entry of free virions.⁵⁸⁸ Cell-to-cell spread⁴⁴⁹ within the liver could circumvent antibody responses, and data from *in vitro* culture on human hepatoma cell lines support this mode of spread,⁶³⁰ suggesting that virus spread *in vivo* is relatively resistant to neutralizing antibody compared with infection with free virions, yet is dependent on the same key entry factors (HCV envelope, CD81, SR-BI, OCLN, and CLDN family members).⁷⁹ These data are supported by the observation of foci of infection during *in vitro* culture, suggesting that this is a potential mode of local spread; however, it is clear that humoral immune pressure drives HCV evolution during chronic infection,³⁸² suggesting that a major component of spread during chronic HCV infection remains subject to antibody-mediated neutralization.

Immune Response

Each component of the host immune response to HCV is balanced in some way by viral components. As a result, multiple viral proteins (depicted in Figs. 27.1 and 27.2, with a detailed

functional discussion in Chapter 25) have immune-evasive roles in addition to more direct functions in the viral life cycle. These include Core (capsid), E1 and E2 (envelope), NS3-NS4A (serine protease), NS5A (polyfunctional phosphoprotein), and NS5B (RNA-dependent RNA polymerase).

Innate Immune Response

The innate immune response is of great importance in control of HCV infection,²¹⁴ and the virus has evolved a variety of mechanisms to evade this response (Fig. 27.3). Interferon signaling is a key component of the innate responses against HCV. Type I, II, and III interferons (IFN- α and IFN- β ; IFN- γ ; and IFN- λ , respectively) have all been shown to be important, early intrahepatic responses in HCV infection.^{60,363,374,626} Type I and II interferons are induced by overlapping signaling pathways. IFN-regulatory factor 3 (IRF3), a latent cytoplasmic transcription factor, can be activated by viral infection and translocated to the nucleus where it induces the transcription of IFN- β . In autocrine and paracrine fashion, IFN- β stimulates activation of the Janus-activated kinase and signal transducer and activators of transcription (JAK-STAT) signaling pathway and synthesis of IFN- α , as well as multiple other antiviral cytokines and chemokines, inhibiting viral replication and orchestrating the subsequent adaptive immune response.²²¹ HCV NS3-NS4A blocks IRF3 activation by proteolytically cleaving TIR domain-containing adapter-inducing interferon- β (TRIF) and mitochondrial antiviral signaling protein (MAVS). TRIF is an adapter protein for the double-stranded RNA (dsRNA) sensing molecule Toll-like receptor 3,³⁷⁷ and MAVS is an adapter protein in the retinoic-acid-inducible gene I (RIG-I) signaling cascade.⁴³⁹ These cleavages underscore the importance of these pathways for antiviral immunity, and impairment of interferon stimulated gene (ISG) expression was reversed by treatment with small-molecule inhibitors of the NS3-NS4A protease.^{377,389,439}

Defects in JAK-STAT signaling have also been described in HCV transgenic mice.⁶⁶ In HCV transgenic mouse and human liver biopsies, impairment of JAK-STAT signaling is linked to hypomethylation of STAT1 and increased expression of protein phosphatase 2A (PP2A).¹⁷⁵ There is also evidence that NS5A protein can stimulate IL-8, inhibit dsRNA-activated protein kinase (PKR), and interfere with 2',5'-oligoadenylate synthetase (2,5-OAS), antagonizing type 1 interferon signaling.^{223,305,344,501} Overexpression of HCV core protein also interferes with IFN signaling, likely through direct interaction with STAT1.^{67,381} Other studies suggest that ubiquitin-specific peptidase 18 (USP18) may be up-regulated by long-term interferon stimulation, blocking activation of ISG15 and suppressing JAK-STAT signaling, and leading to refractoriness to type 1 IFN stimulation.^{401,553} The inhibitory effect of HCV proteins on the interferon activation cascade is incomplete, as gene expression microarray studies have shown type 1 interferon responses in the livers of acutely and chronically HCV-infected chimpanzees.^{60,592} Hepatic levels of ISG expression in chronically infected humans vary significantly for unclear reasons.^{109,552}

Natural killer (NK) cells are also likely to play a very important role in control of HCV infection. NK and natural killer T-lymphocyte (NKT) cells are abundant in the liver and prime cellular immune responses through production of IFN- γ and other cytokines.^{138,639} Binding of the E2 protein to CD81 has been associated with inhibition of NK cell activity.^{138,639} HLA Cw*04 and related haplotypes, which bind inhibitory

FIGURE 27.3. Innate responses to hepatitis C virus (HCV) and their evasion by the virus. Cytoplasmic HCV double-stranded RNA (dsRNA) can be sensed by RIG-I (1), resulting in signaling through mitochondrial antiviral signaling protein (MAVS) and subsequent nuclear translocation of nuclear factor (NF)- κ B and phosphorylated IRF3 that activate an antiviral program including secretion of interferon- β (IFN- β), which has autocrine and paracrine activity; HCV NS3-NS4A protease cleaves MAVS, blocking this signaling.^{213,389,439} Viral dsRNA may be sensed in endosomes by Toll-like receptor 3 (TLR3) (2), which signals via the adapter molecule TRIF domain-containing adapter-inducing interferon- β (TRIF), resulting in nuclear translocation of NF- κ B and expression of IFN- β ; NS3-NS4A protease cleaves TRIF, interfering with this response.³⁷⁷ IFN- β effects depend on the JAK-STAT signaling pathway, which is inhibited (3) by HCV core and NS5A proteins. Inflammatory responses including type I interferons activate host antiviral molecules including protein kinase (PKR) and 2',5'-oligoadenylate synthetase (2,5-OAS), which are antagonized (4) by NS5A. Further details and additional innate responses and evasive mechanisms are described in the text and Table 27.1.

killer immunoglobulin-like receptors (KIR) on NK cells, have been associated with viral persistence.³²⁵ The least inhibitory human leukocyte antigen (HLA)-C-KIR haplotypes are most strongly associated with recovery.

Dendritic cells are critical for orchestration of both innate and adaptive immune responses. Toll-like receptor 7 (TLR7) is expressed by plasmacytoid dendritic cells (pDCs), and pDCs produce type I interferon when co-cultured with Huh-7 cells containing replicating HCV RNA⁶⁰⁶; however, data regarding the effect of HCV infection on pDCs *in vivo* are less clear.^{153,306} HCV may interfere with NK cell activation of dendritic cells,²⁹⁷ and there is some evidence that HCV infection may be associated with impaired peripheral dendritic cell function.^{40,307} This impairment may explain the collapse of the cellular immune response during the transition from acute to chronic infection.^{133,564}

Cellular Immune Response

There is strong evidence that both CD4 and CD8 T-cell responses are critical for control of HCV infection, but there is limited understanding of failure of these responses leading to chronicity. HCV-specific T cells develop rapidly during acute infection and are then detectable for years in blood and liver in individuals after clearance of infection. During chronic infection, stronger polyclonal CD8 T-cell responses in the liver and circulation have been associated with lower circulating HCV loads,^{465,525} though CD8 T-cell responses to HCV epitopes are only detectable *ex vivo* in half of human immunodeficiency virus (HIV)-negative individuals chronically infected with HCV, whether obtained from peripheral blood or liver.^{327,340}

INDUCTION OF T-CELL RESPONSES

HCV-specific T cells typically become detectable in the blood 5 to 10 weeks after infection.^{127,371,573,615,643} In experimentally infected chimpanzees, intrahepatic T-cell responses appear another 4 to 8 weeks later.^{127,615} In intravenous drug users, there is significant overlap in the number of T-cell epitopes targeted during acute infection in individuals with subsequent resolving versus persistent infection outcomes.^{133,564} Even at the height of the response, HCV-specific CD8 T cells rarely target more than 10 epitopes, regardless of outcome, with little evidence of immunodominance.^{133,340} While acute phase CD4 and CD8 T-cell responses are usually detectable regardless of outcome, in individuals who progress to chronic infection, they disappear rapidly and may be less vigorous.^{133,160,259,308,441,564,616,644} HCV-specific T cells produce IL-2 and IFN- γ in individuals who go on to clear infection, and acquisition of full effector function may be a key factor leading to viral control in individuals with spontaneous clearance. In individuals who clear infection, functional effector CD8 T cells peak in the blood just after the initial drop in viremia, usually about 8 to 12 weeks after infection.^{127,251,368,371,615,616}

Anti-HCV T-cell responses are not focused on one viral protein or genomic region, and there is little evidence of immunodominance in general^{133,340,564} when compared with responses to HIV and influenza.^{10,379} Comprehensive analyses of CD4 and CD8 T-cell responses in persons with acute infection, using overlapping peptides composing the HCV polyprotein, have revealed widely dispersed epitopes (Fig. 27.4).^{133,368,564} In persons with certain uncommon alleles, such as HLA-B*27 and HLA-B*57, immunodominant responses to functionally

FIGURE 27.4. Anti-hepatitis C virus (HCV) T-cell epitopes are widely dispersed across the polyprotein during acute infection. The per-person frequency at which responses were detected using ELISpot is indicated for epitopes centered at positions indicated along the polyprotein. CD8 T-cell responses in 12 persons with acute HCV infection are indicated in the upper panel (adapted from two reports, with many outcomes unknown due to early interferon treatment^{133,368}), while the middle and lower panels depict CD4 T-cell responses from 18 subjects with resolving acute HCV and 13 subjects who progressed to chronicity, respectively.⁵⁶⁴ (Middle and lower panels © 2012, Schulze zur Wiesch et al. Originally published in *The Journal of Experimental Medicine*. 209:61–75.)

constrained epitopes have been described,^{469,470,477,549} whereas each person with the more common allele HLA-A*02 targets a few of the dozens of epitopes restricted by that allele.⁶⁷³

ROLE OF T CELLS IN CLEARANCE OF HCV

A central role for T cells in clearance of HCV was illustrated by studies in which T cells (CD4 or CD8) were depleted in chimpanzees in the context of acute HCV infection.^{251,573} Depletion of CD8 T cells, from an animal that had rapidly and spontaneously cleared HCV infection twice, led to prolonged viremia after reinfection, with control occurring when CD8 T cells returned.⁵⁷³ Depletion of CD4 T cells had a somewhat different effect, with widely fluctuating levels of viremia associated with progressive escape mutations at epitopes targeted by previously primed CD8 T-cell epitope responses.^{251,573}

In humans, spontaneous clearance of HCV has been associated with expression of certain major histocompatibility complex (MHC) class I molecules, with various studies showing association with the presence of HLA-B*57, HLA-B*27, HLA-A*11, HLA-A*03, or HLA-Cw*01, and the absence of HLA-Cw*04.^{326,349,420,617} Some of the differences in observed associations may be due to variation in predominant circulating HCV genotypes. The mechanism by which these particular alleles favor clearance of viremia is generally unknown, though there is evidence that some protective alleles bind and present

to T cells epitopes that are particularly immunogenic and/or functionally conserved,⁴⁷⁰ whereas risk alleles may be ligands for inhibitory receptors of NK cells.⁶¹⁷ The latter mechanism is supported by evidence that polymorphisms in NK receptors may also play an important role in HCV clearance.³²⁵

HCV clearance has also been associated with MHC class II genes, particularly DQB1*0301 and HLA-DRB1*1101.^{269,617} In a study using peptides spanning the HCV polyprotein, individuals with resolved infections targeted an average of 10 MHC class II epitopes (range 3 to 28), whereas individuals with chronic infection targeted an average of 1 epitope (range 0 to 8). Epitopes most frequently recognized were in core and nonstructural proteins, which may reflect differences in protein processing or mismatch in other regions between the circulating virus and library peptides.^{150,235,489,560,565} In chimpanzees, a subset of dominant CD4 T-cell epitopes were targeted prior to clearance of infection, and subdominant populations were detected only after clearance.²⁶⁹

MEMORY RESPONSES

Anti-HCV CD8 T-cell responses have been detected in individuals who have been exposed to HCV but have not seroconverted.^{81,340} Studies in chimpanzees have also shown that CD4 and CD8 memory T-cell responses are important for protection against reinfection with HCV.^{48,189,251,400,458,507,573,681} Control of

a second infection is associated with rapid expansion of memory CD4 and CD8 cells.³⁶³ Expansion of HCV-specific T cells was observed 2 to 3 weeks after reinfection compared to 10 to 12 weeks after initial exposure to virus. Depletion of CD8 T cells led to prolonged viremia after reinfection, and depletion of CD4 T cells also led to impaired control, despite the presence of previously primed HCV-specific CD8 T cells.^{251,573} Even more importantly, a recent study demonstrated that reinfected humans tend to develop broader T-cell responses and lower peak viremia and are more likely to spontaneously clear their second HCV infection.⁴⁷⁸

T-CELL RESPONSES DURING CHRONIC VIREMIA

Despite T-cell responses, most HCV-infected individuals remain persistently infected. In individuals who progress to chronic infection, HCV-specific CD8 T cells become dysfunctional, possibly due to CD4 T-cell dysfunction.^{29,258,390,564,675} HCV-specific CD8 T cells obtained from peripheral blood during chronic infection show poor *ex vivo* proliferation and IFN- γ production, low intracellular stores of perforin, and decreased ability to lyse target cells.^{29,258,390,675} These functions are not consistently restored after successful treatment.⁴⁴²

Anti-HCV T-cell responses have been studied primarily in peripheral blood; due to compartmentalization of the T-cell response, such studies are likely to underestimate the breadth and magnitude of intrahepatic responses. Approximately a third of chronically infected individuals have intrahepatic anti-HCV T-cell responses that can be expanded *ex vivo*.^{339,687} Intrahepatic anti-HCV T-cell responses may be associated with lower serum HCV RNA levels, higher degrees of hepatic inflammation, and higher rates of response to interferon-based treatment;^{465,466} thus, responses that contribute to clearance may, if unsuccessful, contribute to injury.¹⁰² In spite of quantitative differences in number and breadth and some differences in phenotype⁵³ of T-cell responses, there are many similarities.⁵⁸⁵ Such inferences from PBMCs have been supported by indirect correlations such as viral escape substitutions in epitopes that were detected in assays of PBMCs.^{134,629}

Many HCV-specific CD8 T cells express the counterregulatory molecule PD-1.^{104,258,541,675} Studies in murine models have shown that PD-1 binds to programmed death ligands 1 and 2 (PD-L1 and PD-L2), and ligation leads to dephosphorylation of signaling molecules downstream of the T-cell receptor (TCR), decreasing T-cell sensitivity to stimulation.^{108,366,476} Blockade by anti-PD-L1 antibodies leads to increased proliferation of both CD8 and CD4 T cells directed against HCV.^{312,455,495,511,524,637} Interestingly, levels of PD-1 expression in acute infection do not appear to correlate with outcome of infection. In model systems, direct activation of CD8 T cells by hepatic parenchymal cells, without help from CD4 T cells, may result in impaired CD8 T cells that express high levels of PD-1.⁶⁹² Some recent studies have suggested that high levels of PD-1 may indicate a high level of immune activation, but not necessarily T-cell exhaustion.¹⁷⁶

T-cell immunoglobulin and mucin domain-containing molecule-3 (TIM-3) may also play a role in modulation of HCV-specific T-cell responses. Expression of both TIM-3 and PD-1 on CD8 cells during acute infection was associated with persistence, and like PD-1, blockade of TIM-3 increased proliferation of HCV-specific CD8 T cells.⁴²¹ Recent studies have suggested that 2B4 (CD244), another inhibitory molecule on

exhausted T cells in the lymphocytic choriomeningitis virus model of chronic infection, may also play a role in modulating HCV-specific CD8 T cells. HCV-specific CD8 T cells show increased expression of 2B4, and 2B4 stimulation reduced the increase in proliferation of HCV-specific T cells usually seen after PD-1 blockade.⁵⁶¹

Interaction with other immune cells likely also modulates antiviral T-cell activity. Liver-infiltrating CD8 T cells may have decreased expression of the co-stimulatory molecule CD86.^{301,355} Regulatory T cells (T_{reg})^{298,376} may modulate HCV-specific T-cell activity, and increased early IL-10 production during chronic HCV infection may drive CD4 T cells to become T_{reg} .²⁰⁹ These CD4CD25^{high} T cells are enriched in peripheral blood during chronic HCV infection and may infiltrate the chronically infected liver, potentially protecting it from injury.^{69,71,92,590,678}

HCV EVASION OF T-CELL RESPONSE

In addition to innate and adaptive host responses that are functionally inadequate for clearing infection, there appears to be selection for HCV mutations that enable response evasion while maintaining adequate replicative fitness to sustain infection. T-cell recognition of HCV is reduced by amino acid replacements that occur *in vivo*,^{103,134,628} and such changes have been correlated with persistence.^{134,181} Multiple cross-sectional studies have shown enrichment of amino acid changes in predicted or confirmed cytotoxic T-lymphocyte (CTL) epitopes among chronically infected individuals with corresponding HLA types.^{207,232,365,521,540,629} Observed mechanisms of reduced recognition during HCV infection (Fig. 27.5) include changes adjacent to epitopes that result in impaired processing for MHC class I presentation,^{329,566} changes in anchor residues that reduce binding affinity for MHC class I,^{134,628} and mutations that affect TCR contact residues.⁶⁸⁶

Amino acid replacements have potential fitness costs that may balance the fitness gain associated with escaping a T-cell response. These substitutions could disrupt functions of HCV proteins or RNA genomic elements^{299,642} or create neoantigen. Loss of protein function in this context has been observed, as have compensatory changes that appear to restore function^{470,477,539,549}; such compensatory changes must be considered when analyzing HCV evolution in the context of an immune response and may be detected in searches for long-range interactions across the genome.¹⁶⁵ Neoantigen could be recognized by other T cells, as has been observed for HIV¹⁵; however, this does not appear to be common in HCV. Lack of recognition of the neoantigen produced by escape substitutions could be due to repertoire fixation,⁶⁸⁶ analogous to the phenomenon of original antigenic sin observed in repeated infections.³³⁴ A novel additional mechanism, the exploitation by HCV of a hole in the human T-cell repertoire⁶⁸⁶ such that the mutant form is not recognized at all, may not be surprising for a virus that has been adapting to humans for a very long time.⁵⁷⁶ Consistent with that mechanism, CD8 T cells specific for epitopes that have escape substitutions, though low in frequency, may express high levels of the memory marker CD127 similar to those found in persons with spontaneous clearance.^{53,311} Escape mutations are not generally observed in epitopes targeted by CD4 T cells^{220,564}; this is not surprising given the indirect role of CD4 T cells in antiviral responses, because a viral variant with an escape substitution in a CD4

FIGURE 27.5. Evolutionary escape from CD8 T-cell response. Mechanisms for escape from recognition from CD8 T cells that have been demonstrated for hepatitis C virus (HCV) include (1) change in a residue affecting proteasomal processing, resulting in C-terminal extensions that cannot be trimmed in the endoplasmic reticulum (ER); (2) change in an anchor residue, resulting in loss of affinity for major histocompatibility complex (MHC) class I; and (3) change in a T-cell receptor (TCR) contact residue.

T-cell epitope might not have a survival advantage relative to nearby variants lacking such a substitution.

Humoral Immune Response

There is increasing evidence for the importance of the humoral immune response in control and clearance of HCV infection. Antibodies against HCV are not absolutely required for clearance of infection, as demonstrated in individuals with congenital agammaglobulinemia.⁴ In individuals with normal humoral immunity, however, binding antibody responses against structural and nonstructural HCV proteins are detectable within weeks to months of infection.^{110,467} Using autologous virus, neutralizing antibodies can sometimes be detected within this same time period.^{170,494}

Envelope proteins E1 and E2 are type I transmembrane proteins that exist on infectious virions as a cross-linked heterodimer.⁶⁶⁰ The structure of E1 is unknown, but recent mutational and computational analysis has produced a draft

structure of E2³⁴² that is supported by functional and antibody mapping studies.^{11,321} HCV envelope binds directly to CD81, and mutational analysis suggests that this binding involves E2 residues in domain I (Fig. 27.6). Although anti-E1 and anti-E2 antibodies can be detected in persons with acute and chronic HCV infection,⁴⁶⁷ almost all neutralizing antibodies target E2 and inhibit entry at a postattachment step.^{272,544,659}

There are numerous direct and indirect lines of evidence to suggest that antibodies against HCV decrease the risk of infection after exposure (see also Passive Immunization section, later). First, there were fewer HCV infections in liver transplant recipients who received immune globulin prior to 1990, the first year that immune globulin preparations were screened for HCV seroreactivity.¹⁹⁹ Second, immune globulin in a randomized controlled study reduced the incidence of sexual HCV transmission.⁴⁹⁷ In addition, inoculum-specific neutralizing antibodies directed at the hypervariable region 1 (HVR-1) reduced infection in chimpanzees; however, HVR-1 variability resulted in breakthrough infection.^{192,194,680} More recently, prophylactic treatment with a broadly neutralizing monoclonal antibody protected against HCV challenge in a human liver chimeric mouse model.³⁶⁹

Neutralizing antibodies may also play a role in modulating ongoing HCV infection. Individuals with primary hypogammaglobulinemia had more rapid progression of disease and poorer response to interferon treatment,⁶³ and individuals with humoral immune defects have fewer amino acid changes in E2.^{73,231}

EVASION OF THE NEUTRALIZING ANTIBODY RESPONSE

The development of pseudotyped lentiviruses for measuring neutralizing antibodies to HCV^{46,385,532} has revealed that chronic infection is associated with significant titers of neutralizing antibodies,³⁸⁵ and a case report of a chronically infected individual showed continuous rounds of escape from neutralizing antibody.⁶⁶⁶ During acute infection, neutralizing antibodies drive sequence evolution, suggesting that they have an impact on fitness *in vivo*, and early appearance of HVR-1-specific and/or neutralizing antibodies is associated with an increased likelihood of spontaneous viral clearance.^{13,170,494,708,709} Individuals reinfected after clearance of infection have lower second peak viremia, increased likelihood of clearance of the second infection, and a more broadly neutralizing antibody response.^{424,478}

The enormous diversity of the virus and tolerance of amino acid changes in E1E2 contribute to escape from this host response (Table 27.1). As with HIV-1, heavy glycosylation of E1 and E2 may provide a “glycan shield” that obscures conserved, functionally important domains (Fig. 27.6).²⁷² During the transition from acute to chronic infection, acceleration of evolution in HCV envelope genes is likely to be due to the appearance of neutralizing antibodies.³⁸² Because they are immunodominant targets of humoral immunity while also tolerating extensive non-synonymous variation, HVR-1 and, to a lesser degree, HVR-2 and the intergenotypic variable region (igVR) contribute to neutralizing antibody escape (Fig. 27.6, marker 2).^{42,47,193,523,659} Antibodies targeting the HVR-1 are common *in vivo*, but, given the variability of the region, they tend to be strain specific. In a study of neutralizing antibody development in acute HCV infection, neutralizing antibody escape mutations were mapped to the HVR-1.¹⁷⁰ Most broadly neutralizing antibodies bind to the E2-CD81-binding site.^{80,320,369,479,544,659} Some of these epitopes are linear, while others are conformational in nature. While the

FIGURE 27.6. Evasion of anti-hepatitis C virus (HCV) antibody-mediated responses. Neutralization of HCV by antibodies can block infection of the cell (1). Binding of neutralizing antibodies (red) can be evaded by variability in the envelope proteins (2) illustrated here in a plot of Wu-Kabat amino acid variability⁶⁹¹ and by dense glycosylation at approximately 15 positions (3). Nonneutralizing antibodies (4, green) and lipoproteins (5) may hinder neutralizing antibody binding to HCV envelope glycoproteins, and delayed exposure of conserved domains until late in the entry process may prevent their recognition on free virions (6). Cell-to-cell transfer of virions is resistant to neutralizing antibodies *in vitro*, suggesting an additional mode of escape for local spread of infection (7). Along the envelope gene map are indicated transmembrane regions (TMs), hypervariable regions (HVRs), intergenotypic variable regions (IgVRs), putative tertiary domains (D1–D3), and CD81-binding residues (vertical lines).

CD81-binding site is highly conserved, many of these broadly neutralizing antibodies can induce escape mutations in HCV cell culture, suggesting that replication-competent escape variants may also exist *in vivo*.³²⁰

Several other mechanisms in addition to antigenic variability may contribute to HCV resistance to antibody-mediated neutralization. It appears that the CD81-binding site may be partially shielded from neutralizing antibodies by the HVR-1 and by N-linked glycosylation (Fig. 27.6, marker 3).^{42,187,272} Lipid shielding of the virion may also play a role, because studies have suggested that some neutralization epitopes are less accessible in particles associated with very low-density lipoproteins (VLDLs) or high-density lipoproteins (HDLs) (Fig. 27.6, marker 5).^{90,665} Additional mechanisms of evasion of neutralizing antibodies may include nonneutralizing antibodies that

bind E1E2 in a manner that interferes with binding of neutralizing antibodies, and postendocytic conformational changes in E1E2 revealing conserved determinants of entry (Figure 27.6, markers 4 and 6, respectively).^{545,705} *In vitro* demonstration of direct cell-to-cell spread of HCV, resistant to most neutralizing antibodies, suggests an additional potential mechanism for immune evasion (Fig. 27.6, marker 7)^{79,630,685}; however, strong evidence for antibody-driven HCV evolution^{170,382} suggests that neutralizing antibodies apply significant selection pressure *in vivo*.

Release from Host and Transmission

HCV RNA has been detected in small amounts in a variety of secreted body fluids including saliva, tears, and urine,^{111,204,430} but transmission primarily results from percutaneous exposure

TABLE 27.1 HCV Proteins Contributing to Persistence

Protein	Immune function	Evasion mechanism	References
Core	TNF- α and lymphotoxin signaling	Interference with intracellular signaling	(107,414,707)

to blood or rarely from mucosal exposure to genital secretions, as discussed in the section on Transmission later.

Virulence

In spite of their extreme heterogeneity, genetic variants of HCV (genotypes and subtypes) have remarkably similar clinical manifestations; for example, there have been no reported outbreaks of acute fulminant hepatitis, and persons infected in common-source outbreaks have displayed a wide range of outcomes.^{151,322} Moreover, efforts to identify viral determinants of fibrosis progression have not revealed consistent associations. Response to treatment is strongly affected by viral genotype, with genotype 1 being relatively refractory to interferon-based therapy as discussed in the Treatment section.

HCV subverts hepatic lipoprotein metabolism (see Virus Assembly section for HCV in Chapter 25), so it is not surprising that steatosis and insulin resistance are common features in HCV infection (see Clinical Features, later).²⁸¹ Multiple studies have found a significantly stronger association between genotype 3 HCV infection and steatosis¹⁵¹ than for other HCV genotypes; this association may be related to genotype-specific disruption of lipid biosynthesis pathways.¹¹⁸ Steatosis is also strongly associated with visceral obesity.⁵ Geographic variation in host factors as well as viral genetic types (see Genetic Diversity, later) could confound association of viral genotype with some manifestations.

During initial HCV infection, the peak of hepatic injury (illustrated by the peak in alanine aminotransferase [ALT] in Fig. 27.7) follows, rather than coinciding with, the peak of viremia.¹⁰² This consistent observation, combined with observations of liver pathology and cell culture, suggests that lysis of HCV-infected cells results primarily from the host antiviral immune response.^{102,115} The association of chronic infection with progressive liver disease and hepatocellular carcinoma is discussed in the Clinical Features section later.

FIGURE 27.7. Patterns of acute hepatitis C virus (HCV) infection, resulting in spontaneous resolution or chronicity. The initial peak of viremia is followed by a peak in alanine aminotransferase (ALT) indicating cytolysis, temporally associated with the detection of cell-mediated responses to HCV that do not differ qualitatively by outcome when measured *ex vivo*.¹³³ Initial level of viremia is higher in those who clear compared with those who later progress to chronic infection.³⁸³

Persistence

When untreated, acute infection with HCV may spontaneously resolve or persist as chronic HCV infection (Fig. 27.7, discussed further in Clinical Features, later). Spontaneous clearance of HCV occurs in approximately one-third of untreated infections. This resolution occurs in the first 2 years and is generally complete, with no residual viral RNA in serum or liver.^{135,424}

Persistent HCV infection occurs in two-thirds of infected persons, is attributable to the evasion mechanisms discussed earlier, and is associated with persistent viremia at a level of 5 to 7 log₁₀ IU/mL in 90% of individuals.⁶²⁷ Spontaneous resolution during chronicity is rare.⁹ Because persistence is marked by high-level viremia and constant evolution in immunocompetent hosts, HCV appears to persist dynamically and there is no evidence of a stable, latent reservoir or archive of previously dominant variants. See Clinical Features of chronic infection, later.

EPIDEMIOLOGY

Morbidity/Mortality

The morbidity and mortality that is most clearly caused by HCV is liver failure and/or liver cancer as a result of chronic infection. In the United States, the Centers for Disease Control and Prevention estimates that chronic HCV infection contributes to 15,000 deaths per year, is the leading cause of liver failure leading to transplantation, and in 2007 superseded HIV as a cause of death (Fig. 27.8).^{184,394,684} HCV-related liver morbidity and mortality increase with older age and greater duration of HCV infection and are expected to rise in the coming decades. Using multistate disease models, one group recently estimated that HCV-related liver failure and cancer will continue to increase until 2020–2023 without widespread treatment.¹⁴⁷ Liver-related mortality is predicted to rise from 146,667 cases in 2000–2009 to 254,550 cases in 2010–2019 and 283,378 in 2020–2029. Reliable worldwide estimates of HCV-related mortality are not available.

HCV-infected persons are at increased risk of more than liver failure. In one study, 10,259 HCV antibody–positive blood donors were compared to donors matched by year of donation, age, gender, and zip code and followed for a mean of 7.7 years.²⁶¹ Compared to the HCV-uninfected donors, the risk of death was 3.13-fold higher in HCV-infected donors, who were more likely to die of not just liver-related but also drug/alcohol-related events, trauma/suicide, and cardiovascular causes. Persons with HCV infection are also at much higher risk of some medical conditions such as mixed cryoglobulinemic vasculitis and porphyria cutanea tarda (see Clinical Features later).^{6,154} The degree to which HCV infection contributes to less specific medical syndromes such as chronic fatigue/arthritis or mental illness is more difficult to establish.

Origin and Spread of Epidemics

HCV infection spread during the 20th century, strongly correlated with expanded production of syringes and their worldwide use for both conventional medicine and illicit drugs.^{172,215,397} Drucker and co-workers¹⁷² estimated that global syringe production rose from 100,000 per year in 1920 to 7.5 million per year by 1952. Widespread use of percutaneous injections for medicinal (and then illicit) drug use antedated appreciation of blood-borne transmission of infection

FIGURE 27.8. Annual age-adjusted mortality rates from hepatitis B and hepatitis C virus and human immunodeficiency virus (HIV) infections listed as causes of death in the United States between 1999 and 2007. Because a decedent can have multiple causes of death, a record listing more than one type of infection was counted for each type of infection. (From Ly KN, Xing J, Kleven RM, et al. The increasing burden of mortality from viral hepatitis in the United States between 1999 and 2007. *Ann Intern Med* 2012;156:271–278.)

and spread HCV throughout the world. This trend explains the 5- to 20-fold increased HCV prevalence rates in certain regions where unsafe injections were widespread and among injection drug users (IDUs) (see Global Burden, Incidence, and Prevalence).²¹⁵ Transfusions of blood products also contributed to HCV infection, especially when donors were paid and no measures were in place to screen blood for infection.³⁹⁹

Prior to the 20th century, HCV infection was probably sustained by percutaneous practices such as scarification rituals and circumcision. This conjecture is supported by evidence of transmission by such practices where they still occur and by molecular clock estimates derived from analyses of worldwide HCV RNA sequences (see Genetic Diversity).^{332,509}

Prevalence and Seroepidemiology

Transmission

HCV can be transmitted by percutaneous exposure to contaminated blood, from a mother to her infant, and by sexual intercourse. There is no evidence HCV can penetrate intact skin, but permucosal transmission has occurred when blood was splashed into eyes.

The likelihood that HCV transmission will occur is directly related to the inoculum and the exposure type. Blood is the usual inoculum, typically contains 5 to 7 log₁₀ copies of HCV RNA per mL, and rarely transmits HCV when viremia is not detected.^{166,627} Although HCV RNA has been amplified from most other body fluids, it is not clear to what extent other body fluids harbor infectious virions.^{204,430,671}

Percutaneous exposures such as unsafe medical procedures and injection drug use are the usual routes of HCV transmission worldwide. HCV transmission almost always occurs following very large percutaneous inocula, such as transfusion of a contaminated unit of blood.^{182,669} However, even very small (less than 10 µL) blood inocula may contain infectious virions to establish infection in a recipient if injected percutaneously, and nosocomial exposure may occur if strict universal precautions are not observed.^{14,293} Blood spiked with an HCV reporter virus was loaded into syringes and viability was recovered from 71% of tuberculin syringes kept at 22°C for 7 days.⁴⁸⁰ This finding correlates with studies of health care personnel with accidental needlestick exposures in whom transmission occurs

in 1% to 2% overall and more often from hollow-bore needles, which contain a larger inoculum than a solid-bore needle.^{330,528} Repeated small-volume exposures to HCV explain the high rates of HCV among injection drug users (see later).

Nonmedical percutaneous exposures such as body piercing and tattooing are plausible risks and epidemiologically linked to HCV prevalence in many countries, though they are likely to be confounded by other risky behaviors in some populations.^{276,336,395,411,426,438,462,506,601}

The frequency by which HCV is transmitted sexually is controversial. On the one hand, long-term monogamous partners of individuals with HCV infection almost never acquire HCV.³⁰ In one study, 895 monogamous sexual partners of persons with chronic HCV infection were followed for over 8,000 person-years, and there were no instances of sexual HCV transmission, despite unprotected intercourse occurring an average of 1.8 times per week.⁶⁵⁴ On the other hand, HCV infection occurs in persons acknowledging high-risk sexual practices (and no other exposure),⁶⁵⁰ and there are multiple outbreaks among HIV-infected men who have high-risk sexual exposures with other men.^{145,648} One speculation is that, as with HIV, the risk of sexual HCV transmission is greater during the acute phase of infection when viremia peaks and prior to formation of neutralizing antibodies. In addition, anal intercourse may cause mucosal tears that promote HCV transmission. Permucosal spread of HCV may also explain the association of HCV infection with intranasal use of cocaine.¹²⁵

HCV transmission from a mother to her infant occurs infrequently (2% to 10%).^{413,527,700} How and when infection occurs in this setting is not known, but risk is increased by maternal HIV infection and/or high HCV RNA levels, prolonged rupture of membranes, and internal fetal monitoring.^{413,624}

Global Burden, Incidence, and Prevalence

There are an estimated 185 million HCV-infected persons in the world, or 2.2% of the human population.^{688,689} There are marked differences in HCV prevalence between regions (Fig. 27.9) and, even within countries, between age and risk groups. Egypt appears to have the highest HCV prevalence, which is as high as 50% in persons born before 1960.²¹⁵ The history of HCV infection in Egypt is exemplary of global

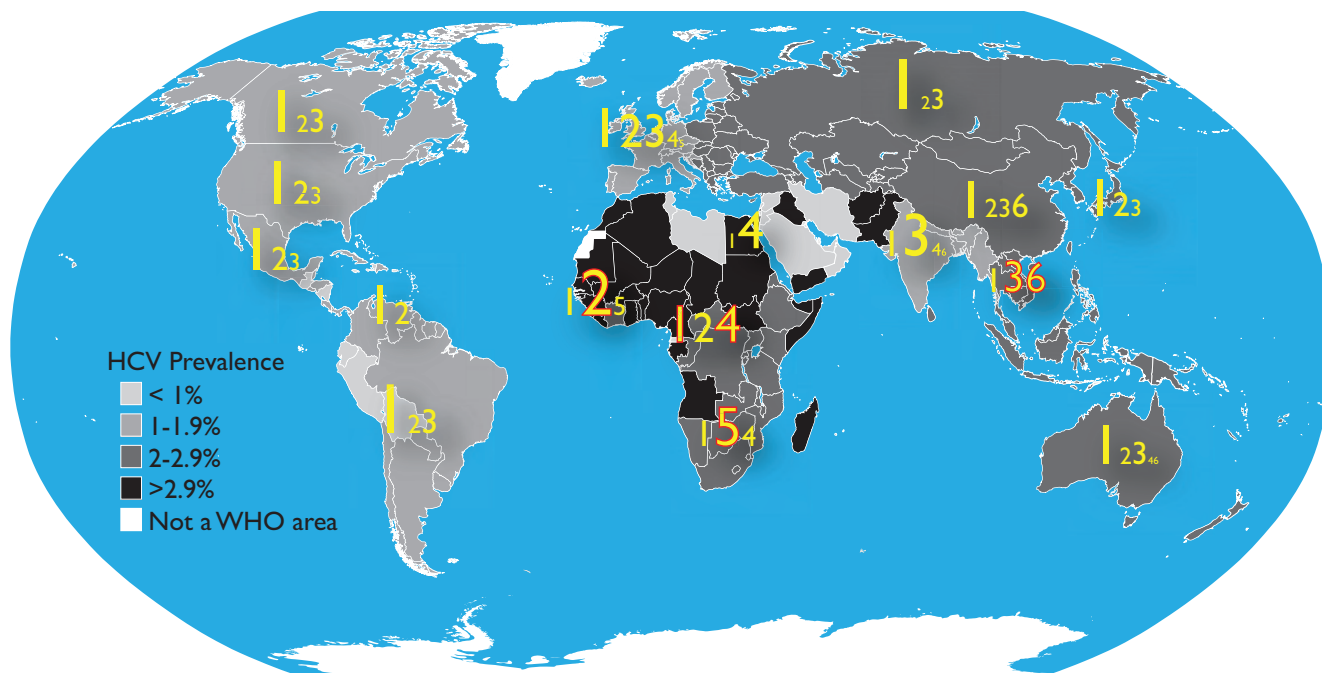

FIGURE 27.9. Map depicting geographic variation in the relative prevalence of hepatitis C virus (HCV) infection and genotypes. Shading of country indicates prevalence. Yellow numerals indicate prevalent HCV genotypes in different regions, with font size corresponding to relative genotype prevalence within each region; red outlining indicates genotypes with greatest intraregional diversity. HCV prevalence is highest, and genetically most diverse, in Africa. Genotype 1 is prevalent worldwide, whereas genotypes 4 and 5 are almost exclusively found in north-central and southern Africa, respectively. Genotype 7 (provisionally assigned and not depicted) has been reported very rarely in persons with epidemiologic links to central Africa. (HCV prevalence estimates adapted from World Health Organization. Global burden of disease [GBD] for hepatitis C. *J Clin Pharmacol* 2004;44:20–29, with permission. Relative genotype prevalence within each region based on sources cited in the text.)

transmission patterns. From the 1950s to the 1980s, the Egyptian Ministry of Health embarked on a campaign to eradicate schistosomiasis infection by intravenously administering tartar emetic to millions of citizens.⁵⁸⁹ The effort, commended at the time as a public health model, occurred before there was widespread appreciation for blood-borne transmission of infectious agents. HCV was transmitted extensively because of the widespread reuse of insufficiently cleaned injection equipment.²¹⁵ Consequently, the prevalence of HCV infection can exceed 50% in persons alive during that campaign while being 1% to 2% in those born after. In addition, more than 90% of HCV infections in Egypt are genotype 4, which make up less than 10% of genotypes in most other regions of the world.⁵²⁰

There is molecular and epidemiologic evidence of similar transmission patterns elsewhere. In studies modeling HCV sequences, Tanaka and co-workers⁶¹⁰ estimated rapid expansion of HCV-1b in Japan in the 1920s, in Europe in the 1940s, and in the United States (HCV-1a) in the 1960s.⁶¹⁰ Population data from southern Italy show that the HCV prevalence is 1.3% in subjects younger than 30 years and 33% in those older than 60 years of age; the odds of infection were doubled in those who recalled reusable glass syringe use.²⁶⁰ Thus, as mentioned earlier (in Origin and Spread), it appears HCV was widely transmitted worldwide during the 1900s due to stepped-up production of syringes and their worldwide use both for conventional and illicit drugs.^{172,397,509}

The overall prevalence of HCV infection in Europe is 1% to 2%. However, country-specific rates vary considerably, with

the lowest HCV prevalence (less than 0.5%) reported from Sweden, Germany, and the Netherlands while prevalence rates of 2% to 3% have been reported in some Mediterranean countries.²⁷¹ There is less information on incident HCV infection. Although HCV surveillance is required in European countries, new infection information is restricted to symptomatic events (which are the minority of HCV infections) and thus data on trends and comparisons across regions are crude. Overall, because procedures to screen blood donations were implemented, most new infections in Europe are linked to injection drug use or recent health care exposure.⁴⁰⁸

United States Prevalence and Incidence

In the United States, an estimated 3 million persons have chronic HCV infection. Several key epidemiologic trends explain the incidence and prevalence of HCV infection. As in other parts of the world, unsafe medical injections probably contributed to an early expansion of HCV prevalence following World War II. Transfusion of blood and blood products caused new HCV infections until 1992, when the most effective screening measures were adopted. However, it was the epidemic of injection drug use from the 1950s to the 1980s that caused most HCV infections in the United States. Whereas there were probably fewer than 500,000 persons with chronic HCV infection in the early 1950s, by the mid-1990s there were an estimated 3.5 million persons with chronic HCV infection and another 1 million to 1.5 million who had recovered.³¹ Much of that epidemic spread was due to injection drug use.

Not only does injection drug use cause most HCV infections in the United States, but also most injection drug users have been HCV infected. HCV infection generally occurs within the first years of initiating the illicit use of injected drugs with annual incidence rates of 10% to 30%.^{135,228,266} In one cohort, 80% of subjects acknowledging 2 or more years of injection use were infected with the virus, a prevalence that was higher than that of HIV or HBV infection.^{229,625} Early acquisition of HCV is probably related to the practice of older (infected) IDUs teaching new (uninfected) initiates by demonstrating first on themselves and then on the new initiate.²²⁸ Although sharing of needles and syringes causes some HCV transmission, Hagan and co-workers²⁶⁵ estimated that 37% of new cases were due to sharing of other equipment.

After peaking in the 1980s, HCV incidence has dropped markedly in the United States.⁹⁸ Elimination of transfusion-related transmission contributed to the reduction in incidence. However, most of the decline is attributed to a reduction of HCV due to injection drug use that is not fully explained.¹⁹ However, because HCV serology remains positive in most instances even when viremia is cleared, the 20-year surge in HCV incidence among persons born between 1945 and 1964 remains serologically evident.

The best data on HCV prevalence in the United States come from the serial National Health and Nutrition Examination Surveys (NHANES).³² By testing blood collected from a subset of persons representing households in the United States around 1990, it was estimated that 4.1 million individuals had been infected with HCV, or 1.6% of the general population. Approximately two-thirds of those infected were born between

1945 and 1965. The survey was repeated 10 years later and showed the same number of HCV-infected individuals in the same age cohort that was 10 years older. Omitted from this survey were nearly 2 million incarcerated persons in the United States, who probably represent another 250,000 to 500,000 HCV-infected persons.³⁹ The prevalence of HCV infection in the United States is also higher among racial minorities than in Caucasian Americans, and greater in African Americans than in Mexican Americans. In non-Hispanic Blacks 40 to 49 years of age, the HCV prevalence was 14% compared to a general population prevalence of 1.6%. HCV infection was detected in only 1% of those 20 to 29 years of age.

Genetic Diversity

Genetic variability is one of the most remarkable features of HCV, contributing to evasion of host immune responses and complicating development of diagnostics, therapeutics, and effective vaccines. HCV genomic sequences can be clustered phylogenetically into related groups (genotypes and subtypes), are distinct between individuals, and are highly variable within each infected individual at any given point in time (i.e., quasispecies diversity^{314,406}) and over time (i.e., quasispecies divergence).

Global Diversity of HCV

Soon after HCV was discovered, it was apparent that genetically distinct strains were prevalent in different geographic areas. International standards for nomenclature established six major genotypes that are phylogenetically distinct, and subsequent reports have resulted in the proposal of a seventh genotype (Fig. 27.10).^{248,346,451,530,577} Within genotypes, phylogenetically

FIGURE 27.10. Phylogenetic tree of representative sequence from the seven proposed genotypes of hepatitis C virus (HCV). Full-genome nucleotide sequences were aligned and analyzed using a maximum likelihood model with estimation of invariant sites and modeling of variable rates using the gamma distribution, with bootstrap re-sampling to confirm support for each genotype cluster. Reference isolates H77 (AF009606) and JFH-1 (AB047639) are indicated. Subtypes of genotype 1 (1a, 1b, 1c) are indicated for illustration.

FIGURE 27.11. Genetic variability of hepatitis C virus (HCV) by genomic region. Using an alignment of full-genome sequences from all seven proposed genotypes, the polyprotein open reading frame (ORF) was analyzed using VarPlot (described in⁵²³) to calculate mean pairwise nonsynonymous distance in a sliding window of 50 codons at intervals of 10 codons. For intergenotype comparisons (blue), there are 21 curves representing each pairwise comparison among the seven genotypes. For genotypes having at least two subtype representatives, there is a curve for each pair of subtypes (red). There is one curve representing mean intrasubtype distance for each subtype having at least four available sequences (green), including subtypes of genotypes 1, 2, 3, 4, and 6; for subtypes having many full-genome sequences, 10 were identified randomly.

distinct clusters may be found that are called subtypes. Clinically, HCV genotypes and subtypes are very similar (see Virulence), though they vary in responsiveness to interferons (genotypes 1 and 4 are less responsive) and, in more complex ways, in susceptibility to direct-acting antiviral agents (see Treatment).

The pairwise distance between genotypes ranges from 29% to 34% for genomic nucleotide sequences and 24% to 33% for amino acid sequences spanning the polyprotein. The protein-coding differences between genotypes are not uniformly distributed across the genome; rather, they are greatest in the E1, E2, p7, NS2, N-terminus of NS4B, and V3 region²⁸⁷ of NS5A, and most conserved in core (blue curves in Fig. 27.11). As that figure illustrates, the contours of pairwise distance are remarkably consistent between genotypes, reflecting neutral evolution as a dominant force in the divergence of genotypes.⁵⁷⁶ Even in the most variable regions (e.g., HVR-1, positions 384 to 410 in the polyprotein using standard genome numbering³⁴⁵), there are severe constraints on amino acids with regard to specific amino acids⁴¹⁵ and biophysical properties.⁴⁸⁸

Variation within genotype (i.e., genetic distance between pairs of subtypes) is about half of the intergenotype diversity, with similar regions of divergence and conservation (red curves in Fig. 27.11); a notable exception is the N-terminus of NS4B, the significance of which is unclear. Variation within subtype (green curves in Fig. 27.11) is more restricted, yet remarkably consistent considering that each tracing represents one subtype

from widely divergent genotypes (1, 2, 3, 4, and 6, which sufficient representatives). Hypervariable region locations that differ among genotypes suggest different selection pressures.²⁸²

Potentially confounding genotype assignment and diagnostics is recombination, which is a dominant mode of evolution in HBV and HIV.^{531,579} Intergenotype recombination has been reported in HCV sequences,^{59,300,302,373,474} and standards for confirmation and nomenclature of recombinant forms are available.³⁴⁶ While recombination among HCV subtypes has clearly occurred *in vivo* and hybrid genomes can be generated *in vitro*,^{248,498,559} this appears to be a rare occurrence given how often distinct HCV genomes simultaneously infect the same host.^{56,580,658} HCV recombination may be limited by superinfection exclusion, which has been demonstrated for HCV *in vitro*.⁵⁵⁸

Because intergenotypic recombination is rare, phylogenetic trees obtained from any segment of the genome will reflect genotypic clustering seen on the full-genome tree, on a scale determined by the variability in that segment of the genome.⁵³⁰ By international consensus,³⁴⁶ the reference genomic regions for HCV genotype/subtype assignment are core/E1^{86,128} and NS5B⁵⁹¹ (see Diagnosis section).

Global Molecular Epidemiology of HCV

Accurate estimation of the relative prevalence of HCV genotypes in a region depends on population-based sampling,^{33,452,520} which is rarely performed. Nonetheless, it is clear that HCV genotypes

are nonuniformly distributed among geographic regions, with dominant features depicted in Figure 27.9.^{131,323,347,464,575}

Genotype 1 is the most widely dispersed worldwide, and phylodynamic analyses are consistent with global expansion in the population and dispersion from 1940 to 1980 and suggest that subtype 1b may have disseminated, possibly in blood products, earlier than subtype 1a.^{397,509} These trends are corroborated by other studies,^{354,536} and subtype 1a is often associated with recent or ongoing drug use in North America and northern Europe.^{55,135,241,452}

Independent analyses of sequence data from other countries in the western hemisphere are consistent with expansion of epidemics during the second half of the 20th century but involving a wider variety of subtypes.^{25,360} Taken together, these studies do not suggest that HCV subtypes differ significantly in terms of transmissibility or association with specific routes of transmission; rather, specific HCV subtypes appear to dominate epidemics as a result of founder effects, and the presence of highly diverse variants of one genotype in a region suggests a local origin.⁵⁷⁶

The epidemic in Egypt²¹⁵ is dominated by subtype 4a but includes diverse subtypes of genotypes 1 and 4,^{514,520} perhaps reflecting its proximity to Central Africa where genotypes 1 and 4 appear to be endemic.^{216,338,427,460,473,482,672} and may share a common origin.^{461,547} Genotype 2 is highly diverse in West Africa, where subtype boundaries can be indistinct, suggesting a local origin of this subtype.^{96,295,538} In Southeast Asia, genotypes 3 and 6 appear to be epidemic, including among IDUs, with subtypes 1b and 2a associated with older infections.^{428,506,578,631–634} (note that in 2005, sequences that had been assigned to subtypes 7a, 8a, 9a, 10a, and 11a were reclassified as subtypes 6d, 6k, 6h, 3k, and 6g, respectively.⁵⁷⁷) Genotype 5 is found in southern Africa, with limited dispersal.²⁶

Origins of HCV

Available evidence summarized in the previous section suggests that HCV is endemic in widely separated regions of the globe. While nonprimate hepaciviruses have been discovered recently in dogs and horses,^{89,309} those isolates are very distinct from HCV, and their origin, prevalence, and tropism are not known.

HCV genotypes appear to have arisen hundreds or perhaps thousands of years ago.^{397,509,583} Without sequence data older than 50 years to “calibrate” such molecular clock analyses, phylogenetic saturation at the HCV genotype level may preclude accurate estimation of the age of HCV.⁵⁷⁶

Quasispecies Variability: Mechanisms

HCV exists in each infected host as a swarm of genetically related but distinct variants, collectively called a quasispecies.^{162,163,177,314,406} This characteristically diverse set of viruses in an individual arises from one or more “founder” sequences from the predictably diverse quasispecies present in the donor(s), selected randomly or based on phenotypic characteristics by a transmission bottleneck that is poorly understood.⁸⁸

Diversity is generated by mutations introduced by the NS5B RNA-dependent RNA polymerase, which lacks a proof-reading function and has an estimated error rate of 10^{-3} to 10^{-5} per nucleotide per replication cycle.^{45,174} Enhancing this diversity is the high rate of viral replication, with 10^{10} to 10^{12} virions produced per day.⁴⁶⁸ This dynamic, error-prone replication is likely to generate a vast array of mutants every day.⁵³⁵ Because

each HCV genome is produced by the error-prone NS5B polymerase and the number of intracellular replication events (from positive to negative, and negative to positive strand) is at least two but could be larger, each infected cell can generate a diverse population of viral genomes. In contrast, HIV undergoes a single round of error-prone cDNA synthesis per infected cell, with subsequent proviral replication (during cell division) and RNA genome synthesis by host DNA and RNA polymerases, respectively.³⁸

Due to neutral drift and sequential selection events (addressed in the next section), HCV quasispecies sequences have motifs that gradually change over time and during passage among individuals, making sequence analysis suitable for forensic and epidemiologic linkage studies.^{243,273,322,484}

Assessment of a complex quasispecies can be confounded by methodologic artifacts. Nucleic acid contamination of specimens and analytical intermediates is a common problem, which can be reduced (if not completely eliminated) by taking appropriate precautions.³⁵⁷ Amplification in multiple cycles, as with the polymerase chain reaction, can introduce sequence artifacts and distort the frequency distribution of sequence variants. These phenomena can inflate or suppress estimates of diversity and evolutionary change and must be considered at all stages from specimen selection and processing through analysis and interpretation.^{384,582,664} The biological site of specimen selection may also affect the results due to compartmentalization,^{91,396,459,562,569} though the limitations of quasispecies sampling may confound such analyses, and the biological implications of compartmentalization remain controversial.

Quasispecies Evolution During Acute HCV Infection

A diverse viral population, under influence from a variety of selection pressures in a complex host environment, is an ideal situation for viral adaptation in a Darwinian manner.⁶⁸⁰ The quasispecies is shaped by positive selection pressure from the host (see Immune Response) and negative selection pressure due to functional constraints imposed by requirements of the viral life cycle (see Chapter 25 for discussion of essential protein motifs and constrained RNA structures at both ends of the genome); therefore, each host's HCV quasispecies directly reflects dynamic aspects of both the host and pathogen.

During acute HCV infection, the diverse quasispecies may be targeted by cellular and humoral immune responses (see Immune Response), which have the potential to reduce the fitness of variants carrying epitopes they recognize and therefore apply positive selection pressure. In people studied during the first months of acute HCV viremia, this selection pressure has been observed in individual epitopes,⁶²⁸ and more broadly as an excess of amino acid replacements in CD8 T-cell epitopes (studied in nonenvelope genes, to avoid confounding by antibody responses).^{134,614} Detailed analysis spanning the HCV polyprotein at multiple time points in four subjects displayed the same phenomena and also demonstrated that nontargeted substitutions represented reversions to the subtype consensus sequence at a rate that was directly related to the conservation of that site in reference sequences.³⁵¹ In that study, the rate of mutation in nonenvelope genes declined during the transition to chronicity, consistent with progressive T-cell dysfunction.^{133,541,564} Some escape mutations require compensatory changes to restore fitness,^{470,539} possibly accounting for additional changes observed during acute HCV infection that

do not fall within targeted epitopes.^{134,351} In comparison with HIV, HCV evolution during acute infection is relatively limited, reflecting CD8 T-cell dysfunction, HCV genomic inflexibility, or both.⁴⁹⁶

The envelope (E1E2) region of the HCV genome is highly variable (as noted earlier) and has a much higher rate of evolution within hosts than other regions of the genome.²⁵² Humoral immune responses directed against envelope genes *E1* and *E2* have the potential to neutralize HCV, and the HCVpp and HCVcc systems provide the means to correlate E1E2 evolution with neutralizing antibody responses (see section on the Humoral Immune Response). HCV escape from neutralizing antibodies⁶⁶⁶ drives the evolution of envelope sequences during acute infection.¹⁷⁰ This is contrasted with relative stasis of HCV

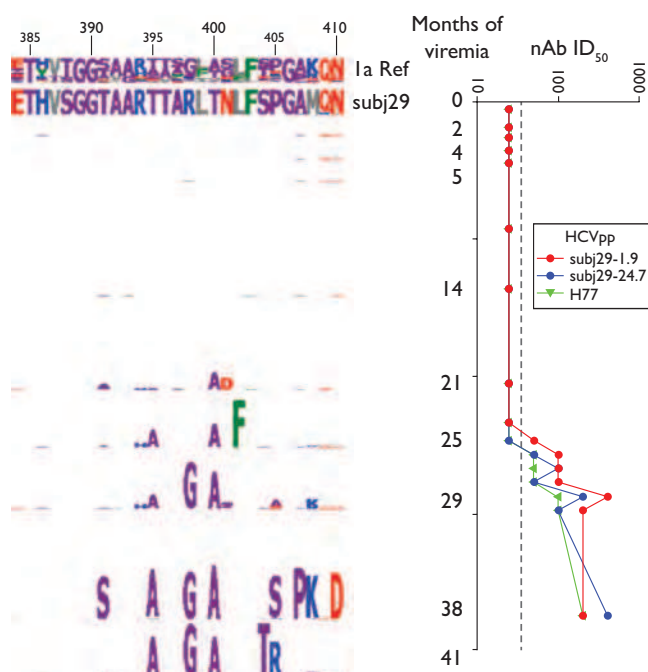

FIGURE 27.12. Evolution of hypervariable region 1 (HVR-1) during the transition from acute to chronic infection. HVR-1 evolution (left panel) correlated with neutralizing antibody (nAb) responses (right panel) in subject 29 (subj29) from the BBAASH cohort¹³⁶ studied from initial viremia (month 0) to chronicity. Type 1 sequence logos²⁴⁷ were used to demonstrate the variability among 388 reference sequences (1aRef) as well as the initial viral quasispecies (subj29, month 0). Amino acid sequence positions are indicated according to H77.³⁴⁵ For months 2 through 41, type 2 logos²⁴⁷ were used to compare amino acid sequences to month 0 sequence, with the height of each amino acid determined by the \log_2 unlikelihood of an amino acid at a given position relative to the initial sequence. To determine nAb infectious dose 50 (ID₅₀) titers, autologous HCV pseudoparticles (HCVpp) expressing E1E2 from month 2 and month 25 visits, as well as HCVpp-H77, were incubated with serial twofold dilutions of autologous plasma. When 50% neutralization was not detected at the starting plasma dilution of 1:50 (dashed line), the result was recorded as one-half this value, a titer of 1:25. (From Liu L, Fisher BE, Dowd KA, et al. Acceleration of hepatitis C virus envelope evolution in humans is consistent with progressive humoral immune selection during the transition from acute to chronic infection. *J Virol* 2010;84:5067–5077. Copyright © 2010, American Society for Microbiology.)

envelope sequences in persons with severely impaired humoral immunity^{73,231,348} and in chimpanzees with poor anti-E2 responses⁴⁹ even during 8 to 10 years of chronic viremia.⁵²² Both stasis and driven evolution are illustrated by HVR-1 evolution in a subject with acute HCV infection progressing to chronicity (Fig. 27.12) in whom neutralizing antibody responses were not detected in the first 2 years of high-level viremia, during which there was no evolution of HVR-1, whereas there was rapid evolution following the detection of neutralizing antibodies.³⁸² Delayed onset of neutralizing antibody responses is typical in those developing persistent HCV infection^{13,170,494,708,709} and appears to explain the acceleration of envelope evolution during the transition from acute to chronic infection.³⁸²

Common-source outbreaks (like the one illustrated in Fig. 27.13) facilitate examination of HCV evolution with respect to host–pathogen interactions and provide strong evidence for nonrandom evolution.^{521,614} HLA allele-specific adaptations of HCV subtype 1b in the Irish outbreak (due to HCV contamination of anti-D immunoglobulin, which occurred in 1977–1978) were distinct from previously identified adaptations in other populations with HCV subtype 1a and 3a infections, suggesting HCV subtype-specific pathways for evolution.⁴²⁰ Study of this cohort revealed a protective effect (associated with spontaneous clearance) of HLA-A*03, and the “footprints” of this response have been observed in HLA-A*03⁺ members of the anti-D immunoglobulin HCV infection cohort; additional study demonstrated that escape mutation was associated with impaired viral replication *in vitro*.²⁰⁷

Implications for Virologic Inference *In Vitro*

In vitro HCV replication systems have provided important insights regarding the viral life cycle, but these observations depend primarily on a very limited set of isolates growing in cell lines with impaired innate immunity³²⁴; most human isolates of HCV do not propagate in cell culture, for reasons that are not clear. *In vivo* models that support replication of more diverse isolates in hepatocytes (rather than hepatoma cell lines) are described in Chapter 25 (HCV Experimental Systems section) and may enable investigation of a more representative variety of HCV strains.

CLINICAL FEATURES

Acute HCV

Acute HCV infection is usually asymptomatic,^{135,448} though a minority of persons will present with more typical symptoms of acute viral hepatitis (malaise, fatigue, anorexia, nausea, abdominal pain, jaundice, dark urine, and sometimes pale stool). While HCV can cause fulminant hepatitis, this presentation is rare.^{190,246,304,398,690,693,698} In general, the latent period (from exposure to symptoms or laboratory abnormalities) is approximately 7 weeks (range 1 to 16 weeks).⁴⁴⁸ In many cases, the only sign of acute infection may be elevation of “hepatic transaminases”^{1,135,661} (ALT and aspartate aminotransferase [AST] from damaged or dead hepatocytes; these enzymes may also be released from nonhepatic cells, particularly AST from cardiac or skeletal myocytes, in association with other conditions).

Most exposures that result in HCV infection are percutaneous (see Transmission), after which hematogenous infection of the liver is presumed to occur. Viremia is detectable within days⁴⁴⁸

FIGURE 27.13. Phylogenetic analysis of hepatitis C virus (HCV) 18 to 22 years after common-source outbreak, using 10 complementary DNA (cDNA) clones from each study subject to obtain the sequence of a 698-nt region spanning the E1/E2 junction. “Inoculum” indicates 20 clones from inoculum source plasma (10 each from 2 specimens) and a full-length clone (AF313916) obtained in an independent study of this material using smaller amplicons. (From Ray SC, Fanning L, Wang XH, et al. Divergent and convergent evolution after a common-source outbreak of hepatitis C virus. *J Exp Med* 2005;201:1753–1759. Copyright © Ray SC et al, 2005.)

and reaches levels of 10^5 to 10^7 IU/mL within weeks. A decrease in viremia, 1 to 2 weeks later, is associated with a sharp rise in hepatic transaminase levels in blood. This sharp rise is thought to result from immune-mediated cytolysis as adaptive responses to HCV develop (Fig. 27.7),^{2,48,135,191,448,571} with more severe hepatitis and higher initial viremia being associated with higher rates of spontaneous clearance of viremia.^{234,383,661} When treatment is not instituted and spontaneous clearance does not occur within 12 months, late spontaneous resolution is rare.

Predictors of Spontaneous Clearance

Spontaneous clearance of HCV RNA usually occurs within 6 months of infection and is associated with having overt symptoms of hepatitis, non-African descent, and lack of HIV infection.^{234,661} The recognition that a linked set of alleles surrounding the IL28B gene (encoding IFN- λ 3) was strongly associated with success of interferon-based therapy²³³ (see Treatment, later) was echoed by the discovery that the same protective genotype was associated with spontaneous recovery from acute HCV,⁶²³ apparently independent of viral genotype.^{353,515,623} The protective IL28B genotype is more frequently found in Asians and least frequently among persons with African ancestry, in keeping with the clinically observed effect of race.⁶²³ The mechanistic basis of these observations remains unknown.⁴¹

Chronic HCV

For the 60% to 85% in whom spontaneous resolution does not occur, chronic HCV infection is a heterogeneous condition, with highly individual manifestations and rates of progression (Fig. 27.14).²⁴⁵ Associated morbidity and mortality

occur almost exclusively when the disease progresses to cirrhosis and end-stage liver disease that may manifest as hepatocellular carcinoma (see subsection later). Chronic HCV infection is characterized by high-level viremia and fluctuating hepatic inflammation and transaminase levels,^{331,492,683} yet chronically infected people typically have few symptoms that are directly attributable to HCV infection. It is difficult to establish a causal

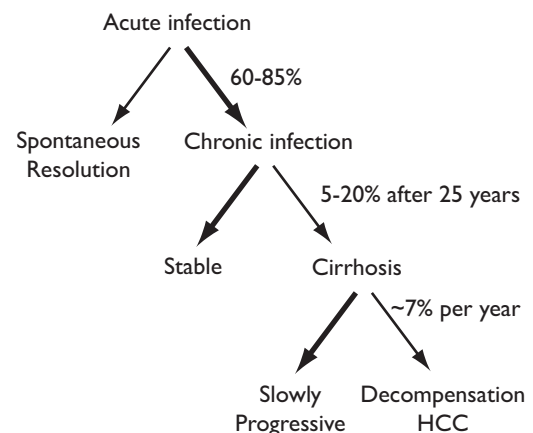

FIGURE 27.14. Progression of hepatitis C virus (HCV) infection. Most HCV infections are persistent and stable, but a minority will progress to cirrhosis within 20 to 30 years. Of those with cirrhosis, most are slowly progressive, but 7% per year will develop either hepatocellular carcinoma (HCC) or decompensated liver disease.^{291,550}

FIGURE 27.15. Histology illustrating progression of hepatitis C virus (HCV)-related liver disease. **A:** Normal portal tract (hematoxylin and eosin [H&E] stain). **B:** Portal inflammation (H&E stain). **C:** No fibrosis (trichrome stain). **D:** Bridging fibrosis (trichrome stain). **E:** Cirrhosis (trichrome stain). **F:** Hepatocellular carcinoma (HCC) (H&E stain). (Courtesy of Michael Torbenson, MD.)

relation between HCV and nonspecific symptoms, though they do tend to improve after successful therapy.^{58,212,586}

The level of HCV RNA in the blood tends to be stable over long periods of time within 1 log₁₀ of 10⁶ IU/mL in 90% of individuals. Conditions associated with modest increases include HIV infection, male gender, and increasing age and body mass index, whereas lower levels may be found in those with ongoing HBV infection and more advanced stage of liver disease.^{21,125,288,621,627,635} Although the HCV RNA level in the blood is correlated with the level in the liver,⁶⁶⁸ there is not a strong correlation between HCV RNA level and fibrosis progression.

Chronic HCV infection is associated with varying degrees of chronic inflammation and steatosis. Lymphocytic infiltrates are typically found in periportal regions of the liver (Fig. 27.15), though these do not correlate strongly with liver disease progression.⁵⁶⁷ For reasons that are not clear, many individuals will not develop significant fibrosis despite decades of high-level viral infection, while others have more production than resorption of collagen, also initially in the periportal region. This process may be stable or progress to formation of septae that expand to form bridges between lobules, and further expansion may result in the severe scarring and regeneration that characterize cirrhosis. Increasing portal venous pressure may lead to portal hypertension and neoplastic transformation may lead to hepatocellular carcinoma, hallmarks of end-stage liver disease.

Although people of African descent are more likely to develop chronic HCV than Caucasians, they appear to have

a milder course, with less inflammation and progression to fibrosis.^{137,613} One potential explanation for this is differences in frequencies of alleles near certain genes such as *IL28B* that are known to affect clearance and may modulate inflammation, though the mechanisms remain poorly understood.

Alcohol consumption is frequent in persons with chronic HCV and is strongly associated with liver disease progression.^{12,493} Along with its well-known hepatotoxicity, alcohol use is associated with reduced access to and early discontinuation of HCV treatment.²³ Elimination of alcohol consumption should be attempted to reduce complications in all persons with chronic HCV.^{24,237,443,584,695}

Chronic HCV infection is also associated with metabolic dysfunction including insulin resistance, type 2 diabetes, lipid derangement, and steatosis that may be more common in (but not exclusive to) persons infected with HCV genotype 3 (see Virulence, earlier).^{129,281,412,423,463} This association is stronger for HCV than for HBV, suggesting that the mechanism may be specific to HCV.^{572,682} Potential contributing mechanisms to metabolic dysfunction in HCV include down-regulation of hepatocyte insulin receptor substrate 1⁷⁵ and glucose transporter 2³¹⁰ and up-regulation of PP2A (see Innate Immune Response, earlier).^{57,175}

Flares of hepatitis (with elevated serum transaminases and/or bilirubin), common in HBV infection,⁴⁹¹ are rare in chronic HCV and should prompt a search for other causes. For example, acute HAV infection during chronic HCV infection may be associated with severe acute hepatitis, including liver failure⁶⁵⁶; for this reason, persons with chronic HCV infection should be vaccinated for HAV and HBV if susceptible.²⁴

Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) is a growing problem in countries like the United States with relatively recent HCV epidemics and is a major established problem in countries like Japan and Egypt where the epidemic of HCV infection occurred 10 to 20 years earlier.⁶¹⁰ Because cirrhosis is often unrecognized, and HCC causes few symptoms until advanced, screening for cirrhosis and HCC is an important aspect of HCV management. Unfortunately, there are few effective, inexpensive screening tools. Serum testing for α -fetoprotein (AFP) has limited diagnostic utility.⁸²

Unlike HBV, which is associated with a substantially elevated risk of HCC at all stages of infection, the association of HCC with HCV primarily arises after a person develops cirrhosis.^{83,146,550,581} While a direct pathogenetic role of HCV in HCC cannot be dismissed,^{101,196,225} and studies in which the core protein was overexpressed under control of a strong promoter have suggested potential for induction of proto-oncogenes and suppression of apoptosis,^{105,107,112,414,517–519,551,574,604,707} the data are conflicting,⁴⁸³ and chronic inflammation may be sufficient to trigger HCC in those cases that precede cirrhosis.⁴⁵⁶

Extrahepatic Manifestations

Although the liver is the principal site of HCV replication, chronic infection is associated with a wide variety of extrahepatic manifestations.²⁶² A common feature of these conditions is chronic inflammation.

Essential mixed cryoglobulinemia, a condition in which cold-precipitating immune complexes are deposited in multiple organ systems, is strongly associated with HCV infection,

though other inflammatory conditions may be implicated. Manifestations often include purpuric rash, weakness, and joint pain but may also include Raynaud syndrome and vasculitis complicated by membranoproliferative glomerulonephritis and neuropathy.^{94,404,440} HCV tests are positive for anti-HCV antibodies and HCV RNA in a large proportion of affected individuals,⁶ HCV treatment can result in remission,^{93,201} and rituximab-mediated B-cell depletion may augment therapeutic response.⁵⁴² The chronic stimulation of B cells implicated in HCV-related cryoglobulinemia⁵⁴³ may also explain the elevated risk (approximately 2.5-fold) of non-Hodgkin lymphoma¹⁴⁴; mechanistically, the potential for HCV E2 to cross-link the B-cell receptor with the co-stimulatory CD19/CD21/CD81 receptor complex may play a role in development of lymphoma (reviewed in⁶⁶²).

Porphyria cutanea tarda (PCT), characterized primarily by disorders of the skin (blistering, hyperpigmentation) and nails (onycholysis) worsened by sun exposure and complicated by scarring, is associated with liver disease and is caused by reduced activity of uroporphyrinogen decarboxylase. It is a multifactorial disease, potentiated by mutations in the *HFE* gene (associated with hereditary hemochromatosis and found in 15% of persons with PCT), as well as HCV infection, alcohol, and estrogen use—all of which should be evaluated in persons presenting with PCT.⁷²

Other conditions that may be observed at increased frequency include detection of antithyroid antibodies and, in some studies, increased prevalence of thyroiditis even before interferon therapy (see also Adverse Effects of Peginterferon and Ribavirin Therapy, later).^{121,140,157,173,636} The association between chronic HCV infection and thyroiditis has been supported by a meta-analysis, though the mechanism remains unclear.^{27,28}

DIAGNOSIS

Clinically, HCV is suspected in persons with otherwise unexplained liver disease. In asymptomatic persons, this infection should be suspected in any person reporting risk factors for infection (see Epidemiology, earlier) or having elevated hepatic transaminases even in the absence of known risk factors, because the infection is highly prevalent. Because of shared risk factors and increased severity of disease, the U.S. Public Health Service recommends HCV testing for all HIV-infected persons upon entry into health care. Because more than two-thirds of persons with HCV infection in the United States were born between 1945 and 1965, the U.S. Public Health Service has recommended that everyone in that “birth cohort” be tested once for HCV infection. The cost-effectiveness of birth cohort testing has already been demonstrated.⁵²⁶

Differential Diagnosis

Other viral causes of acute hepatitis (described in Clinical Features, earlier) include the named hepatitis viruses (HAV, HBV with or without the delta hepatitis agent, or hepatitis E virus [HEV]), yellow fever virus, and a wide range of viruses with broader tropism including Epstein-Barr virus (EBV) and cytomegalovirus (CMV). In immunocompromised hosts, adenovirus and other agents with broad tropism can also cause

hepatitis. Nonviral causes of acute hepatitis include leptospirosis, tuberculosis, rickettsia and rickettsia-like organisms, numerous toxins (alcohol, acetaminophen, isoniazid, and *Amanita phalloides* toxin being prominent), anoxia/hypoperfusion, and autoimmune disease.

Chronic hepatitis may be caused by HBV and occasionally HEV (in immunocompromised hosts), as well as toxoplasmosis, autoimmune hepatitis, and nonalcoholic steatohepatitis.

Laboratory

The recommended approach for diagnosis of HCV infection is testing for HCV antibodies by enzyme immune assay (EIA). When the screening EIA is positive, the next step is usually to test for HCV RNA to establish that there is ongoing infection.²³⁷

Serologic Testing

The standard screen for HCV infection is anti-HCV EIA,²⁴ which detects antibodies to recombinant HCV proteins core, NS3, NS4, and NS5 (see Fig. 27.2).^{113,417,457} Additional antibody testing can also be performed using recombinant immunoblot assay (RIBA),⁶⁵³ which indicates separately the reactivity to antigens that are tested together in the EIA. RIBA is not an independent confirmatory test. Instead, the results indicate whether the antibodies detected on EIA are to HCV or due to nonspecific cross-reactivity.²⁵⁵ In the situation with a positive HCV EIA and negative HCV RNA result, a positive RIBA indicates that there was indeed prior HCV infection, which may have resolved spontaneously (or from treatment). In that setting a negative RIBA would imply the EIA was falsely positive. The signal strength of EIA may also provide an indication of the specificity of the result,^{20,486} though there is no clear cut-off value⁵⁶³ and current versions of the EIA interpreted according to manufacturer specifications have a specificity of greater than 99%.¹²²

Current versions of HCV EIA have increased sensitivity to about 97%^{132,647} and become positive within 4 to 8 weeks of infection.^{44,135,255} Because specificity is not 100%, positive tests in low-risk individuals may be false-positives, and additional testing such as HCV RNA may be needed.^{237,255} Clearance of HCV viremia (spontaneously or after successful treatment) is associated with decreasing antibody levels, sometimes below the level of what would be considered positive on EIA (seroreversion),^{372,607} which can complicate inference of past events.

Early reports of false-negative EIA tests in immunocompromised individuals¹⁰⁰ have been addressed in third-generation immunoassays, resulting in a very low rate of false-negatives even in HIV infection and dialysis settings^{512,618}; nevertheless, RNA testing should be used if suspected on the basis of elevated risk or hepatic transaminases.^{512,598}

Viral Nucleic Acid Detection and Quantitation

Direct viral testing currently depends on detection of the viral genome in plasma or serum, with concentrations expressed in terms of international units (IU).⁵⁴⁶ HCV RNA detection methods use reverse transcriptase-polymerase chain reaction (RT-PCR) (qualitative and quantitative), transcription-mediated amplification (TMA), and branched DNA (bDNA) for signal amplification. Approved RT-PCR assays have linear ranges from 1.7 to 7 log₁₀ IU/mL, while bDNA has somewhat lower sensitivity but greater reproducibility.⁹⁵ Although TMA

has been shown to detect low-level viremia in some specimens that are negative by RT-PCR, TMA and RT-PCR assays appear to have equivalent utility in detecting HCV RNA during or at the end of treatment to predict sustained virologic response (SVR).^{74,447} Though most assays have targeted the 5' UTR due to its relatively high conservation, it is feasible to detect or quantitate HCV RNA by targeting the extremely conserved 3' terminus of the genome.¹⁷¹

HCV Genotype Determination

HCV genotype is the strongest single biological predictor of HCV treatment success.²⁴ Commercially available assays depend on amplification of targets near the 5' end of the genome and use sequencing or reverse hybridization to determine genotype (and, in some cases, subtype). Mixed infections occur but are uncommon. The gold standard for genotype determination is phylogenetic analysis of nucleotide sequences obtained from a phylogenetically informative genomic region; by international consensus, either the E1 or NS5B region may be used for definitive assignment.^{128,577,591}

Liver Disease Staging

Because the progression of HCV-related liver disease is highly variable, staging is important for informing treatment decisions, lifestyle modification, and prognosis. Although the liver biopsy remains the reference standard for staging and provides a wealth of information beyond fibrosis stage, it is invasive and expensive, and other modalities are gaining prominence as they are validated.

Liver biopsy is the standard reference tool for assessing liver fibrosis grade (inflammation) and stage (fibrosis). Tissue examination may detect other causes of liver disease, as well as conditions such as iron overload and steatosis that are important contributors to HCV-related liver disease and may help guide therapy. Histologic stage is assigned on a standard scale, with widely used examples including Batts-Ludwig,⁵⁰ International Association for the Study of the Liver (IASL),¹⁵⁶ Metavir, and Ishak.^{51a,289} Scores range from no fibrosis to cirrhosis, staged as 0 to 4 (for Batts-Ludwig, IASL, and Metavir) or 0 to 6 (for Ishak). In addition to cost and discomfort, the value of a liver biopsy is limited by sampling error and imprecision¹²⁰; its value is being reassessed and noninvasive alternatives are being evaluated.

Noninvasive markers of fibrosis offer the potential for more frequent assessment than the standard liver biopsy interval of 4 to 5 years. Serum markers (only some of which are approved by the Food and Drug Administration [FDA]) and sonographic elastography (a measure of liver stiffness, not yet evaluated by the FDA, but widely available in Europe) are most informative at the extremes, whereas intermediate values may not discriminate well between mild and severe fibrosis.^{237,533}

PREVENTION AND CONTROL

Treatment

All currently approved regimens for treating HCV infection include type I interferon, with the highest response rates associated with pegylated interferon (peginterferon) alfa plus ribavirin, with or without a protease inhibitor (reviewed in⁵⁵⁴). While effective in most participants in clinical trials, HCV treatment

TABLE 27.2 Hepatitis C Virus Direct-Acting Antivirals in Current Phase III Studies

Agent	Drug Class
Asunaprevir (BMS-650032)	NS3-NS4A protease inhibitor
Faldaprevir (BI201335)	NS3-NS4A protease inhibitor
Simeprevir (TMC435)	NS3-NS4A protease inhibitor
Vaniprevir (MK-7009)	NS3-NS4A protease inhibitor
Daclatasvir (BMS-790052)	NS5A inhibitor
Sofosbuvir (GS-7977)	NS5B polymerase inhibitor
Silymarin	NS5B Polymerase inhibitor

remains expensive and is associated with significant side effects. When liver transplantation is necessary, HCV infection of the graft is inevitable without treatment.^{188,505,513}

The only direct-acting antivirals (DAAs) currently approved in the United States or Europe for HCV treatment are the protease inhibitors boceprevir³⁵⁶ and telaprevir,^{275,418} which are reversibly covalent inhibitors of the NS3-NS4A serine protease. Additional DAAs are in advanced (phase III) development (Table 27.2), including noncovalent NS3-NS4A protease inhibitors (asunaprevir/BMS-650032, faldaprevir/BI201335, simeprevir/TMC435, and vaniprevir/MK-7009), an NS5A inhibitor (daclatasvir), and NS5B polymerase inhibitors (sofosbuvir/GS-7977 and silymarin).

Goals of Treatment

The principal goal of antiviral therapy is the amelioration or prevention of disease. Because not all patients are affected by HCV in the same way and because there can be serious adverse events, treatment is individualized. In 2009, guidelines for use of peginterferon and ribavirin suggested the benefits of treatment would outweigh the risks for persons most likely to respond (e.g., genotype 2 infection) and those most in need (e.g., significant fibrosis) and those with the fewest complicating medical problems (e.g., no depression). However, because there are so many factors to consider, treatment decisions were often individualized.²³⁷ Recent therapeutic advances have added even more variables, and selection of the patient for treatment remains a highly individualized practice.

The primary goal of therapy is SVR, defined as undetectable HCV RNA 24 weeks after the end of a treatment regimen (Fig. 27.16); SVR appears to represent a cure of infection. This outcome is associated with loss of intrahepatic RNA and histologic improvement.^{62,367,403} The durability of SVR was assessed in a study of 1,343 people from nine randomized multicenter trials who had SVR after interferon-based treatment,⁶⁰⁵ demonstrating that 99.1% remained HCV RNA negative after an average follow-up of 4 years. Whether the 0.9% of persons with recurrent viremia had relapse or were reinfected was not known.

In contrast to SVR, other outcomes are often described as follows (Fig. 27.16): null nonresponse, consistently detectable HCV RNA with less than 2 log₁₀ reduction by week 24; partial response, consistently detectable HCV RNA with reduction by more than 2 log₁₀ at week 24; breakthrough, suppression to undetectable HCV RNA level that becomes detectable again during therapy; and relapse, suppression of HCV RNA to undetectable levels through the completion of treatment

FIGURE 27.16. Outcomes and patterns of treatment response at times during treatment and at end of treatment (EOT). Outcomes (sustained virologic response [SVR], relapse, breakthrough, and nonresponse) are predicted by early patterns of viral response: rapid, complete early, and partial early virologic response (RVR, cEVR, and pEVR, respectively). Dashed arrows indicate subsequent trajectory of viremia. LLOQ, lower limit of quantitation; LOD, limit of detection.

followed by viremia during subsequent follow-up. Nonresponse can be used to describe collectively the null response and incomplete response patterns (i.e., to distinguish from those who achieve viral suppression), though these terms are not used uniformly (nonresponse is sometimes used to refer specifically to null response).

Mechanisms of Action

INTERFERON- α

Type I interferons are antiviral and regulate proliferation and immunity. Encoded by more than 10 IFN- α genes and one IFN- β gene, these proteins bind the type I interferon receptor, a heterodimer of IFNAR1 and IFNAR2¹¹⁴ that signals through the JAK-STAT pathway to induce hundreds of interferon-stimulated genes (ISGs).³¹⁷ Among these ISGs are PKR, 2,5-OAS, and MxA. These ISGs and others are typically up-regulated during acute HCV infection.⁶⁰ Antiviral effects of activated PKR include phosphorylation and inactivation of eukaryotic translation initiation factor 2A (EIF2A) and nuclear localization of nuclear factor (NF)- κ B; in addition, HCV NS5A can bind and interfere with PKR function.²²⁴ Type I interferons also up-regulate MHC class I expression and NK cell killing functions.⁶¹ Currently recommended therapy is based on peginterferon α due to greater efficacy than other interferon preparations currently available.²³⁷ These are derivatives of IFN- α (2a or 2b) to which polyethylene glycol has been added for improved pharmacokinetics and efficacy.^{219,264,402}

Ribavirin

Like type I interferons, ribavirin is broadly antiviral and is effective as a component of HCV therapy; however, its principal mode of anti-HCV action is unclear.⁴⁸⁵ As an inhibitor of inosine monophosphate dehydrogenase and via direct interaction with RNA polymerases, ribavirin may increase the error rate of the HCV RNA-directed RNA polymerase to a level that

induces lethal mutagenesis,¹³⁹ an effect that may be inapparent at high replication levels but may be unmasked in combination therapy.^{161,361} Alternatively, ribavirin may have immunomodulatory effects.⁵²⁹ In clinical trials, the most pronounced effect of ribavirin is reduction of viremia relapse after completion of therapy.²¹⁹

Efficacy of Combination Therapy with Pegylated Interferon and Ribavirin

The standard regimen for treatment of chronic HCV infection is subcutaneous injection of peginterferon α (180 μ g of 2a, or 1.5 μ g/kg of 2b) weekly. Patients take ribavirin orally with half the daily dose each morning and night; those with genotypes 2 and 3 receive 800 mg daily and those with genotype 1 receive 800–1,400 mg based on body weight.²³⁷

Outcomes with the two peginterferon α formulations (2a or 2b) in combination with ribavirin are comparable, with approximately 40% and 80% of previously untreated patients with chronic HCV genotype 1 versus genotype 2 or 3 achieving a sustained virologic response, respectively.^{219,402} The optimal duration of therapy varies by genotype, with genotype 1 requiring 48 weeks of therapy and persons without HIV infection who have HCV genotype 2 or 3 achieving high rates of SVR with 24 weeks of therapy.²⁶⁴

Predictors of Treatment Success During Interferon-Based Therapy

Well-established determinants of clinical response to these drugs include HCV genotype (genotypes 2, 3, 5, and 6 most responsive, genotype 1 least responsive), HIV infection (coinfection less responsive), stage of liver disease (early stage more responsive than cirrhosis), race (Asians more responsive than Caucasians, who are more responsive than persons with African ancestry), age (<40 years more responsive), sex (females more responsive than males), baseline HCV RNA

level (lower levels more responsive), and body weight (lower weight more responsive).^{26,36,52,148,158,167,202,303,409,410,487,640,641,667,702,703,710} Though not uniformly measured, insulin resistance (see Clinical Features, earlier) is strongly associated with failure of interferon-based therapy.^{124,155,646} Within genotype, there appear to be viral determinants of treatment responsiveness, particularly in the NS5A (specifically, the interferon sensitivity determining region, or ISDR¹⁸⁰) and core proteins, summarized in Tavis et al⁶¹¹; inconsistent detection of ISDRs, with differences among distinct populations, may be related to other differences among those populations,⁴⁸¹ with subtler virologic determinants unmasked only when the impact of host genetics is minimized. Long-range correlations spanning the HCV genome^{34,165} might affect treatment response and constrain evolution of resistance,¹⁶⁴ but their biological significance remains to be demonstrated.

It was recently discovered through a genome-wide association study that a series of polymorphisms clustered around the *IL28B* gene (encoding IFN- λ 3) has a major impact on the outcome of HCV treatment²³³ (as well as spontaneous recovery⁶²³), summarized in.⁴¹ The protective haplotype is enriched in Asian populations, uncommon in African populations, and intermediate in Caucasians; this genotype correlates well with overall success rates of interferon-based therapy, explains about half of the effect of race on treatment success, and may explain divergent findings from different races regarding the importance of HCV polymorphisms in ISDR and core noted earlier. Clinical testing for *IL28B* polymorphisms became available within a year of that discovery, ostensibly to assist in prediction of treatment response, yet the mechanism of this effect remains poorly understood. The presence of the protective *IL28B* haplotype is also associated prior to the start of therapy with lower intrahepatic ISG expression,²⁷⁷ which in turn was previously shown to predict treatment success.^{109,552} Taken together, these results suggest that *IL28B* genotype is one of multiple factors contributing to the phenotype associated with treatment response.⁴¹

Uncommonly, HCV infection is detected during the acute phase.³⁹⁸ Compared to chronic infection, acute HCV infection is more responsive to interferon-based treatment with overall SVR rates greater than 80%, and the response is significantly less genotype dependent than during chronic infection.²⁹⁴ A recent meta-analysis supports monitoring for up to 12 weeks after presentation with acute HCV and in those with persistent viremia using interferon-based therapy¹³⁰ such as peginterferon with ribavirin.⁶⁸ Rates of SVR in HIV-infected individuals with acute HCV may be lower.³⁵⁸

Adverse Effects of Pegylated Interferon and Ribavirin Therapy

Most recipients of the combination of peginterferon α and ribavirin experience adverse medication effects. Patients receiving standard doses of peginterferon α -2a or -2b in a large trial (more than 1,000 participants receiving each drug),⁴¹⁹ the following adverse effects were reported: fatigue (63% to 66%), headache (42% to 50%), nausea (36% to 42%), insomnia (39% to 41%), pyrexia (23% to 35%), anemia (34%), myalgia (22% to 27%), neutropenia (26% to 31%), depression (21% to 25%), irritability (25%), or rash (22% to 28%).

Adverse events resulted in early discontinuation of treatment in 13% of those participants and dose reduction in

43%. Serious adverse events (resulting in new or prolonged hospitalization, disability/incapacity, life-threatening complication, or death) attributed to the medications occurred in 4% of participants.

In addition to those mentioned previously, major adverse effects²⁷⁸ reported commonly (greater than 5%) by patients include arthralgia, anorexia, diarrhea, anxiety, poor concentration, memory loss, hair loss, photosensitivity, itching, nasal congestion, and injection site reactions (erythema, pain, or abscess). Hematologic effects are also common, including reduced neutrophil count, hemoglobin (see later regarding anemia), and platelet count. Uncommon (1% to 5%) but significant adverse effects include marked depression and anxiety, relapse of substance or alcohol abuse, severe bacterial infection, and induction of autoantibodies. Similarly, rare (less than 1%) but significant adverse effects include major psychiatric events, neurologic complications, autoimmune disease, cardiac complications, worsening of hepatitis, and renal, cardiac, or pulmonary failure.

The principal adverse effect of ribavirin is hemolytic anemia. The degree of anemia is highly variable, in part due to polymorphisms in the gene for inosine triphosphatase (ITPA); the protective alleles are associated with reduced ITPA activity and intraerythrocyte accumulation of inosine triphosphate, providing potential for pharmacologic intervention that would make ribavirin less toxic.¹⁹⁸ In combination with peginterferon (which contributes to anemia), ribavirin dose reduction is required in 25% of patients treated for genotype 1 infection and must be discontinued in less than 5%.⁴¹⁹

Viral Dynamics

As increasingly potent therapy approaches an abrupt halt in virus production, mathematical modeling has provided increasingly precise estimates of viral dynamics because at steady state (just prior to initiation of therapy) the rate of virion clearance must equal the rate of virion production.^{405,468,490} The implications of viral dynamic modeling include providing testable hypotheses regarding therapeutic mechanisms, evaluating the contributions of immunologic control to therapeutic efficacy, and predicting clinical outcomes including drug resistance.⁵³⁵

Initiation of antiviral treatment is followed by a delay that varies among drug regimens and then a decline in viremia that fits a biphasic decay model.⁴⁶⁸ Current models provide estimates of an HCV half-life as short as 45 minutes (reviewed in¹⁴³). The 7- to 10-hour delay observed following treatment initiation of interferon-based therapy may be due to interferon signaling¹⁴³ and is shortened to 2 hours with DAA-based therapy.²²⁷ The subsequent first phase of decline, lasting 1 to 2 days, is rapid and attributed primarily to viral clearance unmasked by reduced production. A second, slower phase of decline may be attributed to clearance of infected cells (either through cell death or termination of productive HCV infection). Because early viral dynamics are linked to drug efficacy, it is reasonable to expect that they would be predictive of outcome.

In clinical trials, early viral dynamics have been found to predict outcome with sufficient accuracy so that they are now used to guide early therapeutic decisions from stopping rules to adjustments in treatment duration. Increasingly potent regimens have required enhanced precision of these definitions, and such changes are likely to continue.

Early Virologic Response (Week 12 Response)

Lack of HCV RNA suppression at week 12 (lack of early virologic response [EVR]) consistently predicts failure of treatment. When defined as reduction of HCV by at least 2 log₁₀, the proportion of treatment-naïve individuals who went on to achieve SVR in the context of treatment with peginterferon α -2a or -2b was 0% to 3%,^{149,219} and EVR was generally adopted as a “stopping rule” due to futility. The positive predictive value of EVR in those studies was low, with 65% to 72% achieving SVR. When EVR was subdivided into complete EVR (cEVR, lack of detectable HCV RNA at week 12, Fig. 27.16) versus partial EVR (pEVR, EVR with detectable HCV RNA at week 12), the proportion going on to SVR was 74% to 83% versus 21% to 38%, but cEVR was achieved in only 64% to 65% of those treated with combination therapy^{149,219} for mixed genotype cohorts, and in only 40% to 45% of persons with genotype 1.⁴¹⁹

Rapid Virologic Response (Week 4 Response)

Just as slow response is highly predictive of treatment failure, rapid response is highly predictive of treatment success. In treatment-naïve persons with chronic HCV genotype 1, 80% to 92% of patients treated with peginterferon α -2a or -2b and ribavirin who achieved a rapid virologic response (RVR, undetectable viremia at week 4) went on to achieve SVR,^{200,419} though only 11% to 12% of treatment-naïve patients with HCV genotype 1 achieved RVR when treated with peginterferon α -2a or -2b.

RVR is also associated with comparable success rates with shorter durations of therapy. For genotype 1–infected individuals, shortening the duration of peginterferon α -2a therapy from 48 to 24 weeks is associated with higher failure rates overall, but in the subset with RVR the outcomes are comparable.^{264,296} For genotype 2– and 3–infected individuals with early-stage fibrosis and low baseline HCV RNA levels, shortening the treatment duration from 24 to 12 or 16 weeks in those with RVR may be appropriate.²³⁷

Less than 1 log₁₀ reduction in HCV RNA at week 4 (which occurred in 10% to 11% of patients) also had strong negative predictive value in genotype 1–infected patients treated with peginterferon and ribavirin, with less than 5% of these individuals achieving SVR.⁴¹⁹ In contrast, lack of RVR in this setting has a poor negative predictive value.

Boceprevir and Telaprevir

In May 2011, the NS3-NS4A serine protease inhibitors boceprevir (formerly SCH503034) and telaprevir (formerly VX-950) were approved by the FDA for use in combination with peginterferon and ribavirin for treatment of chronic HCV genotype 1 infection.⁵³⁷ These linear tetrapeptide analogs bind to the NS3 protease active site with a ketoamide center that functions as a covalent serine trap.^{380,472}

Short-term monotherapy with these agents demonstrated significant but incomplete reductions in HCV RNA level, and more detailed study of specimens from the telaprevir trial showed rapid emergence of resistance.^{555,556} Clinical trials of boceprevir (recommended dose 800 mg with food every 7 to 9 hours) or telaprevir (recommended dose 750 mg with fat-containing food every 7 to 9 hours), in combination with peginterferon and ribavirin at standard doses, resulted in approximately 70% SVR, compared with 40% SVR in those treated with the prior standard of care.^{275,356,418}

Boceprevir therapy includes a 4-week lead-in phase of peginterferon and ribavirin, followed by addition of boceprevir. The total duration can be fixed at 48 weeks (4-week lead-in plus 44 weeks of triple therapy). Alternatively, treatment-naïve patients without cirrhosis may be treated using response-guided therapy (RGT) during which early HCV RNA dynamics determine treatment duration: if HCV RNA is undetectable at week 8 (week 4 of boceprevir), the duration of triple therapy is 28 weeks (24 weeks of boceprevir); if HCV RNA is detectable at any visit after week 8 but negative at week 24 and subsequent visits, boceprevir is discontinued at week 36 and peginterferon and ribavirin are continued for an additional 12 weeks. RGT is recommended only for treatment-naïve patients without cirrhosis, and all treatment should be discontinued if the HCV RNA level is greater than 100 IU/mL at treatment week 12, or detectable at week 24.²³⁶

Telaprevir is initiated as part of triple therapy and continued for 12 weeks, after which peginterferon and ribavirin are continued to the end of treatment. For treatment-naïve patients without cirrhosis that have an *extended RVR*, defined as HCV RNA undetected at weeks 4 and 12, duration of therapy can be abbreviated at 24 weeks; for others (with cirrhosis and/or slower response dynamics), peginterferon and ribavirin are continued to complete an overall treatment duration of 48 weeks. All treatment should be discontinued if the HCV RNA level is greater than 1,000 IU/mL at week 4 or week 12 or detectable at week 24.²³⁶

In treatment-experienced patients with HCV genotype 1, boceprevir- or telaprevir-containing triple therapy resulted in overall rates of SVR that were much higher than for peginterferon plus ribavirin, 64% to 66% versus 17% to 21%.^{37,704} Not surprisingly, these rates varied depending on the dynamics of the prior treatment response, with 75% to 83% of prior relapsed patients achieving SVR and only 52% to 59% of prior partial responders achieving SVR after triple therapy. Prior null responders (Fig. 27.16) were excluded from the boceprevir trial,³⁷ but in the telaprevir trial 29% of prior null responders achieved an SVR; most prior null responders who did not achieve SVR had detectable treatment-emergent resistance mutations.⁷⁰⁴

Resistance to Boceprevir and Telaprevir

Boceprevir and telaprevir select for characteristic changes at NS3 codons 36 (V to M, A, or L), 54 (T to A or S), 155 (R to K or T), 156 (A to S, T, or V), and 168 (D to N) both *in vitro* and *in vivo*.^{432,612} Based on *in vitro* models of single substitutions, V36A/M is expected to have a modest impact both on resistance (4-fold increased IC₅₀) and replication capacity (less than 10% reduction), A156V/T the greatest impact on resistance (greater than 50-fold increased IC₅₀) and replication capacity (>50% reduction), and the other substitutions are expected to be intermediate between those extremes.⁵⁵⁵ Combined substitutions at codons 36+155 or codons 36+156 have enhanced resistance and fitness relative to the 155 and 156 single substitutions. Changes at other NS3 codons, including 43 and 55, are less consistently observed and may have less-pronounced impact on resistance.

In the pivotal phase 3 trials in which boceprevir was combined with peginterferon and ribavirin, baseline viral sequence data were available for 980 patients treated with boceprevir. Analysis of these NS3 sequences revealed 43 patients (4%)

with pretreatment resistance-associated variants V36M, T54A/S, V55A, and/or R155K.⁴³² The SVR rate in this population was 65% (28/43). Among the 36 patients in this subgroup who were interferon responsive (greater than or equal to 1 log₁₀ reduction in HCV RNA during 4-week peginterferon/ribavirin lead-in therapy), the SVR rate was 78% (28/36), comparable to the 73% to 81% SVR rate observed in the overall population of interferon-responsive patients. Therefore, in this small subpopulation, the response did not appear to be hampered by the presence of high-level resistance mutations at baseline as long as patients were responsive to lead-in peginterferon/ribavirin. In the seven patients with high-level resistance mutations at baseline who were nonresponsive to interferon as defined by a less than 1 log₁₀ reduction in HCV RNA during the 4-week peginterferon/ribavirin lead-in therapy, SVR was not observed. By contrast, in the overall population, 28% to 38% of patients who were nonresponsive to interferon during the 4-week lead-in period achieved SVR. Currently, there is no clinical indication for baseline resistance testing.²³⁶

In agreement with the aforementioned baseline data, the R155K substitution has been observed in untreated individuals with chronic HCV³⁵⁰ and may represent an escape mutant for an HLA-A*68–restricted T-cell epitope.⁵⁴⁸ At baseline and after unsuccessful treatment, R155K resistance substitutions are observed more frequently in persons with HCV subtype 1a infection than those with subtype 1b infection, reflecting a lower genetic barrier for subtype 1a.⁵⁵⁵ Specifically, for subtype 1a codon R155 is AGG, requiring only one nucleotide substitution to become AAG (K), whereas for subtype 1b the same R155 is encoded by CGG and requires two changes to become AAG.

Following termination of unsuccessful treatment with boceprevir or telaprevir, the frequency of resistant variants tends to decay and wild-type variants predominate in peripheral blood.⁶⁰³ Whether the frequency of resistant variants returns to pretreatment baseline or will have an impact on future treatment success is not known. Current understanding of viral dynamics and resistance supports discontinuation of failing DAA-based therapy as early as possible to avoid an increase in the frequency and fitness (through compensatory mutation) of resistant variants, to preserve future treatment options.²³⁶

Adverse Effects of Boceprevir and Telaprevir

Both boceprevir and telaprevir are associated with increased frequency and severity of anemia relative to peginterferon and ribavirin.^{292,504} Management of anemia by reducing ribavirin dose was not associated with a reduced rate of SVR in these trials.²³⁶

Rash is the most prominent adverse effect associated with telaprevir, with rash noted in 56% versus 32% of those receiving telaprevir, peginterferon, and ribavirin versus those receiving only peginterferon and ribavirin, respectively.²⁹² In 4% of cases the rash was severe (involving at least 50% of the body surface area), in 6% of cases telaprevir was discontinued due to rash, and in 1% of cases the entire regimen was discontinued due to rash.

Drug–Drug Interactions

In a manner analogous to (but distinct from) HIV protease inhibitors, preliminary studies reveal that boceprevir and telaprevir have significant interactions with other drugs as a result of metabolism by and inhibition of hepatic cytochromes. The

range of drugs potentially affected is large and likely to change frequently; clinicians must consult authoritative references for specific information about concomitant medications.

Investigational Agents

Discoveries revealing key steps in the life cycle of HCV have provided promising targets for antiviral development, including HCV p7,³⁹³ NS3–NS4A protease, NS3 helicase, NS4B,^{178,179} NS5A,³⁷⁰ NS5B polymerase,⁴²⁹ NS5A–cyclophilin interaction,^{119,208,257,453} and miR122.^{364,657} Drugs discussed here have completed or are currently in phase 3 trials (Table 27.2). A notable challenge for drug design is the NS3 helicase, which has been difficult to target selectively.²¹⁸

NS3 protease inhibitor classes include linear covalent (FDA-approved agents boceprevir and telaprevir), linear non-covalent, and macrocyclic compounds. The pharmacokinetics, potency, and resistance profiles of NS3 protease inhibitors vary. NS3 protease inhibitors currently in FDA phase 3 development (Table 27.2) include two noncovalent linear inhibitors (asunaprevir/BMS-650032 and BI 201335) and two macrocyclic inhibitors (TMC435350 and vaniprevir/MK-7009).

Daclatasvir/BMC-790052 is a potent inhibitor of NS5A that was used, in combination with asunaprevir, in the first interferon-sparing regimen with a significant rate of SVR (36% in prior nonresponders to peginterferon and ribavirin).³⁸⁸ In this small phase 2a study of patients with chronic HCV genotype 1, 4 of 11 patients who received the interferon-sparing regimen had SVR, and 9 of 10 patients who received peginterferon alfa-2a and ribavirin in addition to asunaprevir and daclatasvir had an SVR. Mild to moderate diarrhea affected most patients in both groups but did not require dose modification.

Small-molecule NS5B polymerase inhibitors include active site nucleoside/nucleotide analogs (competitors and chain terminators) and drugs that bind outside the active site. The latter have multiple potential binding sites in the thumb and palm domains of the NS5B crystal structure. GS-7977 (previously PSI-7977), a chain terminator nucleotide analog prodrug,⁴⁵⁰ which has *in vitro* activity against genotypes 1, 2, and 3,³⁵⁹ was recently reported to achieve SVR in some subjects with HCV genotypes 2 and 3 who received an interferon-free regimen.²²⁶

Silymarin, an extract of milk thistle, has been shown to have anti-inflammatory properties,^{502,503} but it has been difficult to assess such studies due to the fact that silymarin is a mixture of many compounds and standardization has been difficult. Silibinin, which is a component of silymarin, directly inhibits NS5B polymerase.⁷

Vaccines

There is no licensed vaccine for HCV, in spite of substantial interest given the high burden of disease worldwide,^{688,689} ongoing community and nosocomial transmission,^{97,358,484} limited access to treatment in populations at highest risk,^{211,425} evidence for protection from passive immunization (see later), and evidence for protective immunity against chronic infection after primary infection in humans^{424,478} and chimpanzees.³⁶³ The two major vaccine categories, prophylactic (preventive) and therapeutic, may share mechanistic features but have different goals and rationales. It is important to note that unlike most viral infections, a prophylactic vaccine for HCV might include a vaccine that allows (typically mild) acute infection but prevents chronic infection.

Passive Immunization

Passive immunization can be highly protective for some viral infections (e.g., hepatitis B virus, varicella-zoster virus), though its role in HCV infection has not been established and no FDA-licensed anti-HCV immune globulin preparation is available. Unlike HBV, HCV viremia was delayed but not prevented in chimpanzees treated with anti-HCV immune globulin postexposure.³⁴¹ Indirect evidence for protection by passive immunization was gleaned from HCV infections that occurred after anti-HCV–positive donations were excluded from commercial immunoglobulin preparations prior to the implementation of nucleic acid testing for HCV.⁷⁸ More recent studies, augmented by pseudoparticle-based neutralization assays (see Humoral Immune Response, earlier)⁴⁶ and use of the chimpanzee model, revealed evidence for passive protection by neutralizing antibodies *in vitro* and *in vivo*.⁶⁹⁹

Investigations of passive immunization have been facilitated by the development of humanized mouse models of HCV entry and infection (see Model Systems In Vivo, earlier). A genetically humanized mouse model demonstrated protection by passive immunization, using entry (without replication) as a surrogate for infection.¹⁶⁸ Similarly, use of the Alb-uPA SCID mouse model with engrafted human liver has demonstrated neutralization *in vivo* by polyclonal serum,⁶⁵⁵ though neutralization may be less efficient *in vivo* than *in vitro*.⁴³⁴ These systems also support identification and evaluation of broadly neutralizing monoclonal antibodies.^{80,238,369} Studies of maternal–infant transmission of HCV, a setting in which passive immunization might be anticipated, has not revealed correlation between protection and the presence of neutralizing antibodies in the serum of mother or child.^{169,435}

Prophylactic Vaccine Development

Natural infection with HCV generates an immune response that is initially robust and is largely maintained in those who spontaneously clear viremia (see Immune Response, earlier). Prior infection does not prevent reinfection in humans^{8,253,478} or chimpanzees,^{87,189} but chronicity is greatly reduced in secondary infections^{254,424,478} even with heterologous challenge.³⁶³ Although a portion of this apparent protection may be due to host differences,^{41,325,617,623} known genetic markers explain only a minority of the clearance phenotype.

A meta-analysis of vaccine studies in chimpanzees (including 63 naïve, 53 vaccinated, and 36 rechallenged animals),¹⁴¹ most of which were challenged with homologous virus, revealed that HCV-specific immune responses were generated and reduced the rate of chronic infection ($p < .001$) in vaccinated animals (28%) relative to naïve animals (62%) and similarly to rechallenged animals (17%). Peak RNA levels and duration of viremia were also reduced by vaccination. Assays for T-cell responses by IFN- γ ELISpot, performed in only a small number of animals, did not predict efficacy; however, vaccine antigens based on structural proteins were significantly ($p = .01$) more protective (14% chronicity) than those containing nonstructural proteins (46% chronicity). This latter finding is at odds with the highly protective effect of prior cleared HCV infection (i.e., rechallenge after exposure to the full genome) and the consistent importance of HLA class I alleles⁴⁶⁹ and CD8 T cells⁵⁷³ in spontaneous resolution. Therefore, past vaccines have not achieved the protection afforded by natural infection, and

further optimization of antigen, adjuvant, vector, route, and/or schedule is needed.

The protective role of antibody responses in HCV infection remains controversial, in part due to data demonstrating an essential role for CD8 T cells in spontaneous clearance⁵⁷³ in association with a strong CD4 T-cell response²⁵¹ and evidence that individuals with congenital agammaglobulinemia can clear infection without treatment.⁴ Additionally, hyperimmune serum appeared to be only partially protective in the chimpanzee model¹⁹⁴ due to breakthrough of minor sequence variants, and the extreme variability of the HCV envelope gene (see Genetic Diversity) may limit the breadth of protection provided by an antibody-based vaccine or passive immunization. Nonetheless, antibodies generated by chimpanzees after two vaccinations with recombinant E1 + E2 from the HCV-1 strain (subtype 1a) neutralized HCVpp and HCVcc constructs with envelope proteins derived from genotypes 1, 4, 5, and 6.⁴³⁷ Similarly, vaccination of mice and macaques with HCVpp displaying E1 and/or E2 from subtype 1a stimulated production of antibodies that neutralized HCV genotypes 1, 2, 4, and 5.²³⁰ E1E2 subunit vaccination of a small number of healthy human volunteers elicited antibody responses that neutralized heterologous isolates.^{217,516,587}

Vaccines that elicit robust T-cell responses without neutralizing antibodies may not prevent new HCV infections, but they may prevent chronic infection²¹⁰ and associated serious complications. As noted previously (see Immune Response), spontaneous resolution is associated with broadly targeted, polyfunctional CD4 and CD8 T-cell responses. Adenovirus serotypes rarely or never found in humans (addressing the problem of pre-existing immunity¹²³) and expressing HCV NS3–NS5B proteins were recently used to vaccinate healthy volunteers, resulting in sustained T-cell responses targeting multiple viral proteins.⁴³ It is not known whether such a vaccine will prevent chronic HCV infection in humans.

Therapeutic Vaccine Development

A therapeutic vaccine, to be used during chronic infection to augment pharmacologic therapy, modulate chronic disease outcome, or clear chronic infection, is an attractive goal for improving the health of many millions of people with limited treatment options. As an adjunct to conventional antiviral therapy, a therapeutic vaccine would have the potential to reduce duration and/or dose of antivirals, thereby reducing toxicity, cost, and failure rate. Evidence of low-level viremia at end of treatment in persons who subsequently experience relapse underscores the potential value of this approach; in addition, suppression of viremia during therapy may optimize the immune system's ability to augment responses that were previously suppressed by the tolerizing effects of chronic viremia.

Therapeutic vaccines have demonstrated modest efficacy in pilot studies, illustrating the challenge of stimulating immune responses to a chronic infection. Humans injected with E1 protein subunit developed anti-E1 responses but no significant change in viremia or inflammation.^{471,676} IC41, a multiepitope peptide-based vaccine, stimulated peptide-specific CD4 and CD8 responses in healthy volunteers,^{205,206} had inconsistent effects on the level of viremia in chronic infection,³³³ and induced HCV-specific T-cell responses near the end of interferon-based treatment without preventing relapse.⁶⁷⁷ TG4040, a modified vaccinia Ankara (MVA) vaccine using an attenuated

poxvirus to express NS3-NS5B proteins, stimulated measurable T-cell responses in a minority of recipients, some of whom had transient reductions in viremia.²⁶³

Prevention of Transmission of HCV

Because the transmission routes of HCV are well defined (see Transmission, earlier), behavioral measures for prevention can be effective if applied consistently. HCV transmission by medical procedures can be stopped by strict observance of infection control protocols.^{239,293,512} Although blood transfusions were once an important route of HCV transmission, transfusion transmission has virtually been eliminated by testing donors for HCV antibodies and RNA.³⁹⁹ Nonetheless, even in some economically developed nations, HCV transmission still occurs in hospitals and traditional medical centers. In one report from Spain, 67% of acute HCV infections were linked to receipt of medical care.⁴⁰⁸ The World Health Organization estimates that unsafe injections continue to cause 2.3 million to 4.7 million new HCV infections each year.²⁸³

HIV Co-Infection with HCV

The complications of HCV are more frequent and severe in persons with HIV, leading to HCV's designation in 1999 as an opportunistic infection,^{99,595} and liver disease related to viral hepatitis continues to be a major cause of death among persons with HIV worldwide.⁶⁷⁴ For these reasons, people with HIV should be screened for HCV upon entry into care, for any unexplained elevation of hepatic transaminases, and periodically in the setting of risky behavior.

Due primarily to shared routes of transmission, approximately one-quarter of persons with HIV infection also have HCV infection.⁶¹⁹ HIV infection increases the likelihood of transmission of HCV from mother to child^{274,624,700} and among men who have sex with men.^{240,249,645,648,649,651,652} After exposure to HCV infection, the likelihood of becoming chronically infected is higher in persons with HIV infection,^{391,424,433,620} and in those with chronic infection, progression to end-stage liver disease is more frequent and rapid in those with HIV.^{242,250,596} HCV RNA levels in persons with HIV are higher than in those without HIV.^{186,621,622,627} There has been concern about evidence of fibrosis progression in the first 1 to 2 years of HCV infection in some cohorts,²⁰³ though pre-existing liver disease could not be excluded, fibrosis has not previously been assessed during acute infection, and longer follow-up is needed to clarify this issue.⁶⁶³

Whether chronic HCV infection alters the course of HIV or the response to antiretroviral therapy is not clear. Greub and co-workers²⁵⁶ suggested that even among the subset of HIV/HCV co-infected persons in whom HIV was fully suppressed by antiretroviral therapy, CD4 lymphocyte responses were reduced compared to HIV-infected controls without HCV. Sulkowski and co-workers⁵⁹⁷ failed to detect an association once the strong interaction of HCV and injection drug use was considered. What is clear is that adherence to antiretroviral therapy is the dominant determinant of clinical outcomes in HIV/HCV co-infected persons.

Even though treatment of HIV in persons with HIV may be complicated by hepatotoxicity,^{3,126,152,244,256,416,475,508,534,593,598,599-600,619} significant complications are rare, therapy can be monitored and adjusted, and antiretroviral therapy appears to reduce liver disease progression.^{54,77,510} Treatment of HCV in

those co-infected with HIV is more complicated due to cytopenias and other toxicities, and concomitant therapies increase the potential for drug-drug interactions, particularly with direct-acting antiviral agents for HCV.⁵⁹⁴ These challenges, and the lower likelihood of SVR in persons with HIV infection (discussed in the Treatment section earlier), underscore the need for safer and more effective antiviral agents for HCV.

PERSPECTIVE

A more detailed understanding of the HCV life cycle remains a high priority; we have limited understanding of the trade-offs between replication and virion production, their basis in the viral sequence, and how these are modulated. Current model systems are incompatible with “wild” isolates, and a robust immunocompetent small-animal model is sorely needed. Our nascent understanding of the systems biology of antiviral immunity is underscored by the puzzle of *IL28B* polymorphisms and HCV: intense study has failed to identify the key genetic determinant and its mechanism, with potentially broad implications for innate and adaptive antiviral immunity; this is made more interesting by the relative lack of effect of *IL28B* polymorphisms on HBV or HIV pathogenesis.⁴⁰⁷ Epidemiology of HCV, including genotype distribution, is rarely obtained on a population basis; more accurate assessment would have a broad impact on treatment and prevention efforts. Although the safety and efficacy of treatment are likely to improve, worldwide eradication of HCV will depend on a multifaceted approach; therefore, development of a vaccine that prevents chronic infection continues to be an important goal.

ACKNOWLEDGMENTS

We acknowledge Michael Torbenson for providing histology images, John Ticehurst for helpful suggestions, and support from NIH R01 DA024565 (S.C.R.) and R01 DA016078 (D.L.T.).

and severe hepatitis and neurologic diseases in mice.^{75,186} It was not until the 1960s, however, that these viruses,^{27,32} as well as certain human respiratory viruses,^{8,391} were recognized to share characteristics that merited their being grouped together. Their most notable common feature, revealed by electron microscopy, was a fringe of widely spaced, club-shaped spikes that projected from the virion surface; these spikes were morphologically distinct from the surface projections of ortho- and paramyxoviruses. The halo of spikes was described as giving the viral particle the appearance of the solar corona, which prompted the name that was adopted for this new virus group.⁷

Over the next 40 years, coronaviruses were studied mainly because they cause economically significant respiratory and gastrointestinal diseases in domestic animals and because they provide unique models for viral pathogenesis. In humans, two coronaviruses were known to be responsible for a substantial fraction of common colds, particularly those that circulate in winter months. This situation changed dramatically with the emergence in 2002 of a devastating new human disease, severe acute respiratory syndrome (SARS), which was caused by a previously unknown coronavirus.^{143,288,440} Research stimulated by the SARS outbreak has led to great strides in our understanding of coronaviruses; by 2005, two additional, widespread human respiratory coronaviruses had been discovered.^{573,615} Moreover, the search for animal virus reservoirs has nearly tripled the total number of identified coronaviruses,^{255,394,616} although most of the recently discovered species are known only as genomic sequences and have yet to be isolated or propagated experimentally.

CLASSIFICATION

The coronaviruses are the largest group within the *Nidovirales* (Fig. 28.1), an order that comprises the families *Coronaviridae*, *Arteriviridae*,⁵²⁴ and *Roniviridae*.¹⁰² The arteriviruses, a small group of mammalian pathogens, are discussed in Chapter 29. The roniviruses, which infect shrimp, and a very recently isolated mosquito-borne virus,^{416,663} which is not yet classified, are currently the only members of the order having invertebrate hosts. Nidoviruses are membrane-enveloped, nonsegmented positive-strand RNA viruses that are set apart from other RNA viruses by certain distinctive characteristics.¹⁹⁴ Their most significant common features are (a) an invariant general genomic organization, with a very large replicase gene upstream of the structural protein genes; (b) the expression of the replicase-transcriptase polypeptide by means of ribosomal frame shifting; (c) a collection of unique enzymatic activities contained within the replicase-transcriptase protein products; and (d) the expression of downstream genes via transcription of multiple

HISTORY

Coronaviruses are enveloped RNA viruses that are broadly distributed among humans, other mammals, and birds, causing acute and persistent infections. Members of this family were isolated as early as the 1930s as the causative agents of infectious bronchitis in chickens,²⁵ transmissible gastroenteritis in pigs,¹⁴²

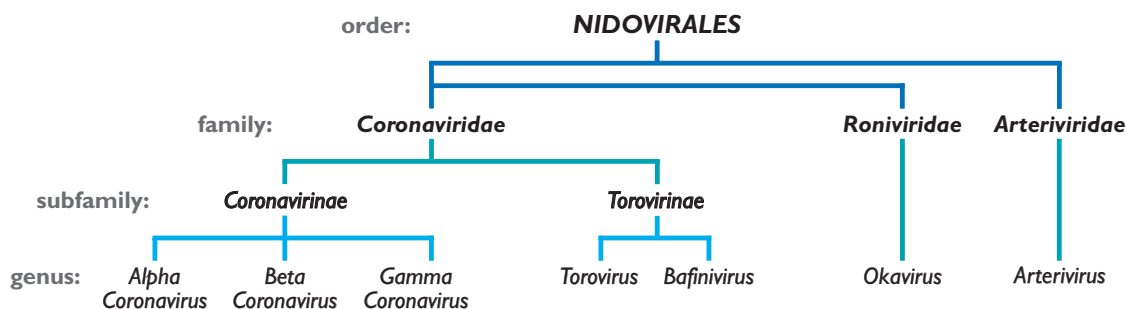

FIGURE 28.1. Taxonomy of the order *Nidovirales*.

3'-nested subgenomic messenger RNAs (mRNAs). This last property has provided the name for the order, which comes from the Latin *nido*, for "nest".¹⁵⁷ It should be noted that the replicative similarities among the three nidovirus families are offset by marked differences in the numbers, types, and sizes of their structural proteins and great variation among the morphologies of their virions and nucleocapsids.

Coronaviruses are now classified as one of two subfamilies (*Coronavirinae*) in the family *Coronaviridae* (see Fig. 28.1). The other subfamily, *Torovirinae*, includes the toroviruses, which are pathogens of cattle, horses, and swine,⁵²³ and the bafiniviruses, whose sole member is the only nidovirus currently known to infect fish.⁵⁰⁵ This chapter will concentrate almost exclusively on the *Coronavirinae*.

Coronaviruses have long been sorted into three groups, originally on the basis of serologic relationships and, subsequently, on the basis of phylogenetic clustering.^{193,195} Following proposals that were recently ratified by the International Committee on Taxonomy of Viruses (ICTV),⁵⁷ these groups—the alpha-, beta-, and gammacoronaviruses—have now been accorded the taxonomic status of genera (see Fig. 28.1). The ICTV classifications have also established rigorous criteria for coronavirus species definitions, in a manner consistent with those used for other viral families. As a consequence, some viruses previously considered to be separate species are currently recognized as a single species—for example, the viruses now grouped within alphacoronavirus 1 or betacoronavirus 1 (Table 28.1). Additionally, the new classification criteria resolve any previous uncertainty about the taxonomic assignment of the virus that caused SARS (severe acute respiratory syndrome coronavirus [SARS-CoV]) as a betacoronavirus.^{153,197,374,473,483,521,534,535}

Almost all alpha- and betacoronaviruses have mammalian hosts. In contrast, the gammacoronaviruses, with a single exception, have been isolated from avian hosts. Several of the viruses listed in Table 28.1 have been studied for decades, specifically those included in the species alphacoronavirus 1, betacoronavirus 1, murine coronavirus, and avian coronavirus. The focus on these viruses came about largely because they were amenable to isolation and growth in tissue culture. However, since 2004, molecular surveillance and genomics efforts initiated in the wake of the SARS epidemic have led to the discovery of a multitude of previously unknown coronaviruses that now constitute most members of this subfamily.⁶¹⁶ Notably, most of the newly recognized species were identified in bats, which constitute one of the largest orders within the mammals. Diverse coronaviruses have been described from bats, principally in Asia but also in Africa, Europe, and North and South

America. These viruses include likely predecessors of SARS-CoV^{308,332} but also four unique species of alphacoronaviruses and three species of betacoronaviruses. Birds have also proven to be a rich source of new viruses. Novel avian coronaviruses have been found to infect geese, pigeons, and ducks,²⁵⁵ and highly divergent coronaviruses recently identified in bulbuls, thrushes, and munias⁶¹⁷ have the potential to define a fourth genus in the *Coronavirinae*. It has been proposed that bats and birds are ideally suited as reservoirs for the incubation and evolution of coronaviruses, owing to their common ability to fly and their propensity to roost and flock.⁶¹⁶

Five of the viruses in Table 28.1 are associated with human disease. The most categorically harmful of these, SARS-CoV, which is discussed at length later in this chapter, does not currently infect the human population. The remaining four human coronaviruses (HCoVs), the alphacoronaviruses HCoV-229E and HCoV-NL63, and the betacoronaviruses HCoV-OC43 and HCoV-HKU1, typically cause common colds. Remarkably, HCoV-NL63 and HCoV-HKU1 were only discovered recently, in the post-SARS era,^{573,615} despite the fact that each has a worldwide prevalence and has been in circulation for a long time.^{461,618} Although generally associated with upper respiratory tract infections, the extant HCoVs can also cause lower respiratory tract infections and have more serious consequences in the young, the elderly, and immunocompromised individuals. In particular, HCoV-NL63 is strongly associated with childhood croup,⁵⁷⁴ and the most severe HCoV-HKU1, -OC43, and -229E infections are manifest in patients with other underlying illnesses.⁴⁶⁰

VIRION STRUCTURE

Virus and Nucleocapsid

Virions of coronaviruses are roughly spherical and exhibit a moderate degree of pleomorphism. In the earlier literature, viral particles were reported to have average diameters of 80 to 120 nm but were far from uniform, with extreme sizes from 50 to 200 nm.³⁸⁹ The spikes of coronaviruses, typically described as club-like or petal-shaped, emerge from the virion surface as stalks with bulb-like distal termini. Some of the variation in particle size and shape was likely attributable to stresses exerted by virion purification or distortions introduced by negative staining of samples for electron microscopy. More recent studies, employing cryo-electron microscopy and cryo-electron tomography,^{21,30,413,415} have produced images (e.g., Fig. 28.2A) in which virion size and shape are far more regular, although still

^aListed viruses are those for which complete genome sequences are available. Novel viruses that have not yet been formally classified include Bulbul coronavirus HKU11,⁶¹⁷ Thrush coronavirus HKU12,⁶¹⁷ Munia coronavirus HKU13,⁶¹⁷ Asian leopard cat coronavirus,¹³⁹ and Mink coronavirus.⁵⁹²

^bRepresentative GenBank accession numbers are given for viruses in each species; in many cases, multiple genomic sequences for a given virus are available.

^cOther viruses included in the species Betacoronavirus 1 are Human enteric coronavirus (HECoV) and Canine respiratory coronavirus (CRCoV), for which only partial genomic sequences are available.

^dOther viruses included in the species Murine coronavirus are Puffinosis virus (PCoV) and Sialodacryoadenitis virus (SDAV), for which only partial genomic sequences are available.

^eOther viruses included in the species Avian coronavirus are Pheasant coronavirus (PhCoV), Goose coronavirus (GCoV), Pigeon coronavirus (PCoV), and Duck coronavirus (DCoV), for which only partial genomic sequences are available.²⁵⁵

pleomorphic. These studies, which examined a number of alpha- and betacoronaviruses, converge on mean particle diameters of 118 to 136 nm, including the contributions of the spikes, which project some 16 to 21 nm from the virion envelope.

Enclosed within the virion envelope is the nucleocapsid—a ribonucleoprotein that contains the viral genome. The struc-

ture of this component is relatively obscure in images of whole virions; however, its makeup has been partially displayed by electron micrographs of spontaneously disrupted virions or of virions solubilized with nonionic detergents.^{59,109,183,269,366} Such studies revealed another distinguishing characteristic of coronaviruses: They have helically symmetric nucleocapsids.

FIGURE 28.2. Coronavirus structure. **A:** Cryo-electron tomographic image of purified virions of mouse hepatitis virus (MHV), reconstructed as described in reference 415. (Courtesy of Benjamin Neuman, David Bhella, and Stanley Sawicki.) **B:** Schematic showing the major structural proteins of the coronavirus virion: S, spike protein; M, membrane protein; E, envelope protein; and N, nucleocapsid protein.

Helical symmetry is common for negative-strand RNA virus nucleocapsids, although it is highly unusual for positive-strand RNA animal viruses, almost all of which have icosahedral capsids. The best-resolved images of the coronavirus nucleocapsid, which were obtained with HCoV-229E, showed filamentous structures 9 to 13 nm in diameter, with 3- to 4-nm-wide central canals⁵⁹; these filaments were thinner and less sharply segmented than paramyxovirus nucleocapsids. However, widely ranging and sometimes discrepant parameters have been reported for the nucleocapsids of other coronaviruses,³⁷⁸ varying with both the viral species and the method of preparation.^{109,183,269,366,476} Thus, further work is needed to clearly define the diameter, symmetry, length, and protein:RNA stoichiometry of this virion component in isolation. More recent coronavirus ultrastructural studies suggest that when packaged within the virion envelope, the helical nucleocapsid is quite flexible, forming coils and other structures that fold back on themselves.^{21,413}

Virion Structural Proteins

Coronaviruses contain a canonical set of four major structural proteins: the spike (S), membrane (M), and envelope (E) proteins, all of which are located in the membrane envelope, and the nucleocapsid (N) protein, which is found in the ribonucleoprotein core (see Fig. 28.2B).

The distinctive surface spikes of coronaviruses are composed of trimers of S molecules.^{30,129,529} S is a class I viral fusion protein⁴¹ that binds to host cell receptors and mediates the earliest steps of infection.⁹⁵ In some cases, S protein can also induce cell–cell fusion late in infection. The S monomer is a transmembrane protein of 128 to 160 kDa, composed of a very large N-terminal ectodomain and a tiny C-terminal endodomain (Fig. 28.3). This protein is inserted, via a cleaved signal peptide,⁶² into the endoplasmic reticulum (ER), where it obtains N-linked glycosylation increasing its mass by some 40 kDa.^{224,487} Comprehensive mapping of glycosylation sites has not been carried out for any S protein; however, an analysis

of the SARS-CoV S protein showed that at least half of its 23 candidate sites are glycosylated.²⁸⁷ The early steps of glycosylation occur co-translationally, and this modification assists monomer folding and proper oligomerization; terminal glycosylation is then completed subsequent to trimerization.¹²⁹ S protein monomer folding is also accompanied by the formation of intramolecular disulfide bonds among a subset of the numerous cysteine residues of the ectodomain.⁴²⁵ The positions of S protein cysteines are well conserved in each coronavirus genus^{2,153}; disulfide linkages have yet to be mapped.

In many beta- and gammacoronaviruses (e.g., mouse hepatitis virus [MHV], bovine coronavirus [BCoV], and infectious bronchitis virus [IBV]), the S protein is partially or completely cleaved by a furin-like host cell protease into two polypeptides, denoted S1 and S2, which are roughly equal in size. Correspondingly, in coronaviruses that do not have detectably cleaved mature S proteins, the N-terminal and C-terminal halves of the molecule are also designated S1 and S2, respectively. S protein cleavage occurs immediately downstream of a highly basic pentapeptide motif,^{2,62,361} and the extent of proteolysis correlates with the number of positively charged residues in the motif.³⁶ The S1 domain is extremely variable, exhibiting very low homology across the three genera and often diverging extensively among different isolates of a single coronavirus.^{181,430,597} By contrast, the S2 domain is highly conserved.¹¹¹ For those coronaviruses in which it occurs, S1–S2 cleavage is a late event in virion assembly and release from infected cells. For many other coronaviruses, an alternative type of S protein cleavage (S2′) takes place during the initiation of infection, activating the molecule for fusion.²⁸ The differing functions of S1 and S2 and the role of proteolysis are discussed later (see the Viral Entry and Uncoating section).

A complete high-resolution structure has not yet been determined for any coronavirus S protein, although a cryo-electron microscopic reconstruction of the SARS-CoV S protein is available,³⁰ and partial crystal structures have been solved for particular S protein domains.^{144,208,323,325,624,630,655}

FIGURE 28.3. Virion structural proteins. Folded and linear representations of the spike (S), hemagglutinin-esterase (HE), membrane (M), envelope (E), and nucleocapsid (N) proteins. The size scale for the linear diagram of S is half of that for the other proteins. In the linear diagram of S, *solid* and *open arrowheads* indicate the S1-S2 and alternative (S2') cleavage sites, respectively. In the linear diagrams of S, M, and N, *red brackets* indicate mapped regions involved in assembly interactions (see the Assembly and Release of Virions section).

Nevertheless, all currently available structural and biochemical evidence accords well with an early proposal that S is functionally analogous to the influenza HA protein.¹¹¹ In this model, the S1 domains of the S protein oligomer make up the bulbous, receptor-binding portion of the spike. The narrow stalk of the spike, distancing the bulb from the membrane, is a coiled-coil structure formed by association of heptad repeat regions (HR1 and HR2) of the S2 domains of monomers (see Fig. 28.3).

The most abundant structural protein in coronaviruses—the M protein^{544,546}—gives the virion envelope its shape. The M monomer, which ranges from 25 to 30 kDa, is a polytopic membrane protein that is embedded in the envelope by three transmembrane domains.^{14,486} At its amino terminus is a very small ectodomain; the C-terminal endodomain of M accounts for the major part of the molecule and is situated in the interior of the virion or on the cytoplasmic face of intracellular membranes (see Fig. 28.3). Although it is inserted co-translationally into the ER membrane, the M protein generally does not bear an amino-terminal signal peptide.^{62,486} For IBV and MHV, either the first or the third transmembrane domain of M alone suffices as a signal for insertion and anchoring of the protein in its native membrane orientation.^{350,363,384} Anomalous, M proteins of the alphacoronavirus 1 species do contain cleavable N-terminal signal peptides, although it is not clear whether these are necessary for membrane insertion.^{263,584} The ectodomain of M is modified by glycosylation, which is usually N linked.^{60,251,402,536,632} However, a subset of betacoronavirus M proteins exhibit O-linked glycosylation, and the MHV M protein has served as a model for study of this type of post-translational modification.^{116,349,419} Glycosylation of M influences both organ tropism and the interferon (IFN)-inducing capacity of some coronaviruses.^{72,113,311}

M proteins are moderately well conserved within each coronavirus genus but diverge considerably across genera. The most variable part of the molecule is the ectodomain. By contrast, a short segment, overlapping the third transmembrane domain and the start of the endodomain, exhibits a high degree

of sequence conservation that is seen even in torovirus M proteins.¹³² Like most multispanning membrane proteins, the M protein has been refractory to crystallization; however, recent cryo-electron microscopic and tomographic reconstructions have provided a glimpse of the structure of this protein within the virion envelope.^{21,413,415} These studies reveal that the large carboxy terminus of M extends some 6 to 8 nm into the viral particle and is compressed into a globular domain, consistent with early work showing that the endodomain is very resistant to proteases.^{61,384,486,490} The observed M structures are likely to be dimers, the monomers of which are associated through multiple interacting regions. M dimers appear to adopt two different conformations: a compact form that promotes greater membrane curvature and a more elongated form that contacts the nucleocapsid.⁴¹⁵

The E protein is a small polypeptide of 8 to 12 kDa that is found in limited amounts in the virion envelope.^{189,344,647} Despite its minor presence, no wild-type coronavirus has been discovered to lack this protein. Engineered knockout or deletion of the *E* gene has effects ranging from moderate¹²⁴ to severe^{293,296} to lethal.^{105,428} Thus, although E is not always essential, it is critical for coronavirus infectivity (see the Assembly and Release of Virions section). E protein sequences are widely divergent, even among closely related coronaviruses.²⁹³ However, all E proteins share a common architecture: a short hydrophilic amino terminus, followed by a large hydrophobic region, and, lastly, a large hydrophilic C-terminal tail (see Fig. 28.3). E is an integral membrane protein,^{100,335,582} but it does not have a cleavable signal peptide⁴⁶⁵ and is not glycosylated. Beta- and gammacoronavirus E proteins are palmitoylated on cysteine residues downstream and adjacent to the hydrophobic region^{38,101,335,354,647}; this modification remains to be found in an alphacoronavirus E protein.¹⁸⁹ The membrane topology of E is not completely resolved. Most evidence indicates that this polypeptide transits the membrane once, with an N-terminal exodomain and a C-terminal endodomain.^{101,420,465,564,582} Contrary to this are reports that E has a

hairpin conformation, placing both of its termini on the cytoplasmic face of membranes,^{12,368} or that E can have multiple membrane topologies.⁶⁴⁸ Also unresolved is the oligomeric state of E protein. The hydrophobic region of the SARS-CoV E protein forms multimers, from dimers through pentamers.^{564,610} A pentameric alpha-helical bundle structure has been solved for this domain,⁴⁴⁹ although it is not yet clear whether this reflects the organization of the native protein.

Residing in the interior of the virion, the N protein is the sole protein constituent of the helical nucleocapsid.²²² Monomers of this 43- to 50-kDa protein bind along the RNA genome in a beads-on-a-string configuration common to other helical viral nucleocapsids (see Fig. 28.2B). However, unlike the nucleoproteins of rhabdo- and paramyxoviruses, the coronavirus N protein provides little or no protection for its genome against the action of ribonucleases.^{366,408} The bulk of the N protein monomer is made up of two independently folding domains—designated the N-terminal domain (NTD) and the C-terminal domain (CTD)—although neither includes its respective terminus of the N molecule (see Fig. 28.3). Crystal or solution structures have been determined for NTDs and CTDs of SARS-CoV, IBV, and MHV.^{76,164,200,234,253,493,555,646} Flanking the NTD and CTD are three spacer segments, the central one of which contains a serine- and arginine-rich tract (the SR region), which was noted to resemble the SR domains of RNA-splicing factors.⁴⁴² Another functionally distinct region of N, the carboxy-terminal domain 3, has been defined genetically.^{236,279,441,442} The spacer segments and domain 3 are each likely to be intrinsically disordered polypeptides.^{66,67} Most of the N molecule, including the NTD and CTD, is highly basic; by contrast, domain 3 is acidic. There is only a moderate degree of sequence homology among N proteins across the three genera, with the exception of a stretch of 30 amino acids within the NTD that is highly conserved among all coronaviruses.³⁸⁰

The N protein is a phosphoprotein,^{272,352,515,542} modified at a limited number of serine and threonine residues. Phosphorylation sites have been mapped for a representative coronavirus from each genus, and targeted sites, collectively, fall in every domain and spacer region of the N molecule.^{55,77,604,619} Thus, a general pattern for N protein phosphorylation cannot yet be discerned, nor have all responsible kinases been identified, although there is evidence linking glycogen synthase kinase-3 to phosphorylation of the SR region.⁶¹⁹ The role of phosphorylation is also not known but is thought to have regulatory impact. Phosphorylation has been suggested to trigger a conformational change in N protein,⁵⁴¹ and it may enhance the affinity of N for viral versus nonviral RNA.⁷⁷

The most conspicuous function of the N protein is to bind to viral RNA. Nucleocapsid formation must involve both sequence-specific and nonspecific modes of RNA binding. Specific RNA substrates that have been identified for N protein include the transcription-regulating sequence (TRS)^{200,412,539} (see the Viral RNA Synthesis section) and the genomic RNA packaging signal^{96,396} (see the Assembly and Release of Virions section). The NTD and the CTD are each separately capable of binding to RNA ligands *in vitro*, and the structures of these domains offer some clues as to how this is accomplished. The NTD consists of a U-shaped β -platform with an extruding β -hairpin, which presents a putative RNA-binding groove rich in basic and aromatic amino acid residues.^{164,200,493} The CTD forms a tightly interconnected dimer, which exhibits a potential

RNA-binding groove lined by basic α -helices.^{253,555} Some work suggests that in the intact N protein, optimal RNA binding requires concerted contributions from both the NTD and the CTD.^{67,235} A significant fraction of nucleocapsid stability also results from interactions among N monomers.⁴⁰⁸ This level of association is generally attributed to the CTD^{67,164,253,646}; however, additional regions of N–N interaction have been mapped to the NTD and to domain 3.^{164,235,253} Another crucial function of N protein is to bind to M protein.^{162,546} This capability is provided by domain 3 of N.^{236,295,585}

A fifth prominent structural protein—the hemagglutinin-esterase (HE) protein—is found in only a subset of the beta-coronaviruses, including murine coronavirus, betacoronavirus 1, and HCoV-HKU1. In virions of these species, HE forms a secondary set of short projections of 5 to 10 nm arrayed beneath the canopy of S protein spikes.^{204,435,550} The 48-kDa HE monomer is composed almost entirely of an N-terminal ectodomain; this is followed by a transmembrane anchor and a very short C-terminal endodomain (see Fig. 28.3). HE is inserted into the ER by means of a cleaved signal peptide and acquires an additional 17 kDa of N-linked glycosylation at multiple sites.^{221,271,640} The assembled protein is a homodimer, the subunits of which are connected by disulfide bonds.²²¹ As its name indicates, the HE protein contains a pair of associated activities. First, it is a hemagglutinin—that is, it has the capability to bind to sialic acid moieties found on cell surface glycoproteins and glycolipids.^{54,272} Second, HE exhibits acylesterase activity with specificity for either 9-*O*- or 4-*O*-acetylated sialic acids.^{274,472,520,590,591} These characteristics are thought to allow HE to act as a cofactor for S protein, assisting attachment of virus to host cells, as well as expediting the travel of virus through the extracellular mucosa.⁹⁹ Consistent with this notion, the presence of HE in MHV dramatically enhances neurovirulence in the mouse host.²⁶⁵ Conversely, the HE protein is a burden to the virus in tissue culture, where its expression is rapidly counterselected.³⁴³ The two activities of the HE protein are strikingly similar to the receptor-binding and receptor-destroying activities found in influenza C virus,^{590,591} and, remarkably, the coronavirus HE gene is clearly related to the influenza C virus HEF gene.³⁵⁹ Moreover, toroviruses also possess a homolog of the HE gene,^{99,305} raising the possibility that all three of these virus groups evolved from a common ancestor.^{359,522} This kinship is further corroborated by the crystal structure of the BCoV HE protein, which reveals separate receptor-binding and acylesterase domains perched atop a truncated membrane-proximal region.⁶⁵⁰ The HE protein thus resembles a squat version of its influenza virus counterpart, shortened because it lacks the fusion domain stalk of the HEF protein.

GENOME STRUCTURE AND ORGANIZATION

Basic and Accessory Genes

The coronavirus genome, which ranges from 26 to 32 kb, is the largest among all RNA viruses, including RNA viruses that have segmented genomes. This exceptional RNA molecule acts in at least three capacities^{50,194}: as the initial mRNA of the infectious cycle (see the Expression of the Replicase-Transcriptase Complex section), as the template for RNA replication and transcription (see the Viral RNA Synthesis section), and as the substrate for packaging into progeny viruses (see

FIGURE 28.4. Coronavirus genome organization. A schematic of the complete genome of MHV is shown at the top. The replicase gene constitutes two ORFs, rep 1a and rep 1b, which are expressed by a ribosomal frameshifting mechanism (see the Expression of the Replicase-Transcriptase Complex section). The expanded region shows the downstream portion of the genomes of two betacoronaviruses (MHV and SARS-CoV), an alphacoronavirus (FeCoV), and a gammacoronavirus (IBV). The sizes and positions of accessory genes are indicated, relative to the basic genes *S*, *E*, *M*, and *N*. MHV, mouse hepatitis virus; ORFs, open reading frames; SARS-CoV, severe acute respiratory syndrome coronavirus; FeCoV, feline coronavirus; IBV, infectious bronchitis virus.

the Assembly and Release of Virions section). Consistent with its role as an mRNA, the coronavirus genome has a standard eukaryotic 5'-terminal cap structure³⁰¹ and a 3' polyadenylate tail.^{302,351,503,599} The genome comprises a basic set of genes in the invariant order 5'-*replicase*-*S*-*E*-*M*-*N*-3', with the huge *replicase* gene occupying two-thirds of the available coding capacity (Fig. 28.4). The replicase-transcriptase is the only protein translated from the genome; the products of all downstream open reading frames (ORFs) are derived from subgenomic mRNAs. The 5'-most position of the *replicase* gene is dictated by the requirement for expression of the replicase to set in motion all subsequent events of infection. The organization of the other basic genes, however, does not seem to reflect any underlying principle, because engineered rearrangement of the downstream gene order is completely tolerated.¹²¹

Dispersed among the basic genes in the 3'-most third of the genome, there are from one to as many as eight additional ORFs, which are designated accessory genes^{378,407} (see Fig. 28.4). These can fall in any of the intergenic intervals downstream of the *replicase* gene,⁶¹⁶ except, curiously, never between the *E* and *M* genes. In some cases, an accessory gene can be partially or entirely embedded as an alternate reading frame within another gene—for example, the internal (*I*) gene of MHV or the *3b* gene of SARS-CoV. Accessory genes are generally numbered according to the smallest transcript in which they fall. Consequently, there is usually no relatedness among identically named accessory genes in coronaviruses of different genera, such as the *3a* genes of SARS-CoV, feline coronavirus (FeCoV), and IBV (see Fig. 28.4). Some of these extra ORFs are thought to have been acquired through ancestral recombination with RNA from cellular or heterologous viral sources. The *HE* gene is the best-supported example of this type of horizontal genetic transfer.³⁵⁹ Two other such candidates are the *2a* gene found in murine coronavirus and betacoronavirus 1, which encodes a putative 2',3'-cyclic phosphodiesterase,^{385,485}

and gene 10 of beluga whale coronavirus, which encodes a putative uridine-cytidine kinase.³⁹⁴ Notably, the *2a* gene has a homolog embedded as a module within the *replicase* gene of the toroviruses,⁵²² which is a situation also consistent with horizontal transfer. The origin of most accessory genes, however, remains an open question. It is plausible that some of them evolved through intragenomic recombination, resulting in gene duplication and subsequent divergence, as suggested for several of the accessory genes of SARS-CoV.²⁴¹

Almost all accessory genes that have been examined are expressed during infection, although their functions are incompletely understood. The protein products of most accessory genes are nonstructural; however, this rule is not without exception. The *HE* protein, the MHV *I* protein,¹⁶⁵ and the products of SARS-CoV ORFs 3a, 6, 7a, 7b, and 9b^{231,407,502,627} are all components of virions. Mutational knockout or deletion of accessory genes has revealed that none are essential for viral replication in tissue culture. Conversely, accessory gene ablation,^{103,115,206} or transfer to another virus,^{452,559} can have profound effects on viral pathogenesis. In some cases, the basis for this is understood to result from interactions with host innate immunity (see the Immune Response and Viral Evasion of the Immune Response section). For other accessory genes, though, potential *in vivo* functions have not yet been elucidated.^{125,165,645}

Coronavirus Genetics

Classical coronavirus genetics focused principally on two types of mutants.²⁹⁹ The first were naturally arising viral variants, particularly deletion mutants, which offered clues to genetic changes responsible for different pathogenic traits.^{430,583,603} The second were temperature-sensitive (*ts*) mutants isolated from MHV following chemical mutagenesis.^{282,477,501,545} Some of these proved to be valuable in analyses of the functions of structural proteins.^{279,360,380,474} However, owing to the large target size of the *replicase* gene, most of such randomly generated mutants

had conditional-lethal, RNA-negative phenotypes. Complementation analyses of these latter mutants yielded early insights into the multiplicity of functions entailed by coronavirus RNA synthesis.^{22,176,177,501} There has been a recent resurgence of interest in classical replicase *ts* mutants, which are currently sorted into five complementation groups, because they can now be fully examined by the tools of reverse genetics.^{138,499,543}

The development of coronavirus reverse genetics proceeded in two phases.¹³⁰ Initially, a method called *targeted RNA recombination* was devised at a time when it was uncertain whether the construction of full-length infectious complementary DNA (cDNA) clones of coronavirus genomes would ever become technically feasible. With this method, a synthetic donor RNA bearing mutations of interest is transfected into cells that have been infected with a recipient parent virus possessing some characteristic that can be selected against.^{279,377,380} In its current form, for manipulation of MHV, the technique uses a chimeric recipient parent virus designated fMHV (Fig. 28.5A). The fMHV chimera is a mutant of MHV that contains the S protein ectodomain from the FeCoV feline infectious peritonitis virus (FIPV) and can therefore only grow in feline cells (see the Virion Attachment to Host Cells section). The restoration of its ability to grow in murine cells, via recombination with donor RNA containing the MHV S gene, enables a strong selection for viruses bearing site-specific mutations^{292,381}; unwanted secondary crossover events distal to the S gene are eliminated owing to the rearrangement of downstream genes in fMHV.¹⁹⁰ Targeted RNA recombination remains a powerful method to recover structural or accessory protein or 3' untranslated region (UTR) mutants.

To obtain access to the major part of the coronavirus genome, however, it was necessary to create full-length cDNAs, despite the barriers presented by the huge size of the *replicase* gene and the high instability of various regions when propagated in bacterial clones. Three innovative strategies were developed to overcome these inherent difficulties.¹³⁰ In the first (see Fig. 28.5B), a full-length cDNA copy of a coronavirus genome is assembled downstream of a cytomegalovirus (CMV) promoter in a bacterial artificial chromosome (BAC) vector, which is stable by virtue of its low copy number.^{5,6} The infection is then launched from transfected BAC DNA through transcription of infectious coronavirus RNA by host RNA polymerase II. This method of initiating infection obviates potential limitations of *in vitro* capping and synthesis of genomic RNA. In the second strategy (see Fig. 28.5C), a full-length genomic cDNA is assembled by *in vitro* ligation of smaller cloned cDNA fragments, some of the boundaries of which have been chosen so as to interrupt regions of instability.^{642,643} The ligation occurs in a directed order that is dictated by the use of asymmetric restriction sites. Infectious genomic RNA is then transcribed *in vitro* and used to transfect susceptible host cells. An extension of this method has demonstrated the construction of a coronavirus genome entirely from synthetic cDNAs.²⁶ In the third strategy (see Fig. 28.5D), the genome of vaccinia virus is used as the cloning vector for a full-length coronavirus cDNA that is generated by long-range reverse transcription polymerase chain reaction (RT-PCR).^{94,561} The cDNA is then amenable to manipulation by the repertoire of techniques available for poxvirus reverse genetics.^{51,94} Infections are launched from *in vitro*-synthesized RNA or else from transfected cDNA

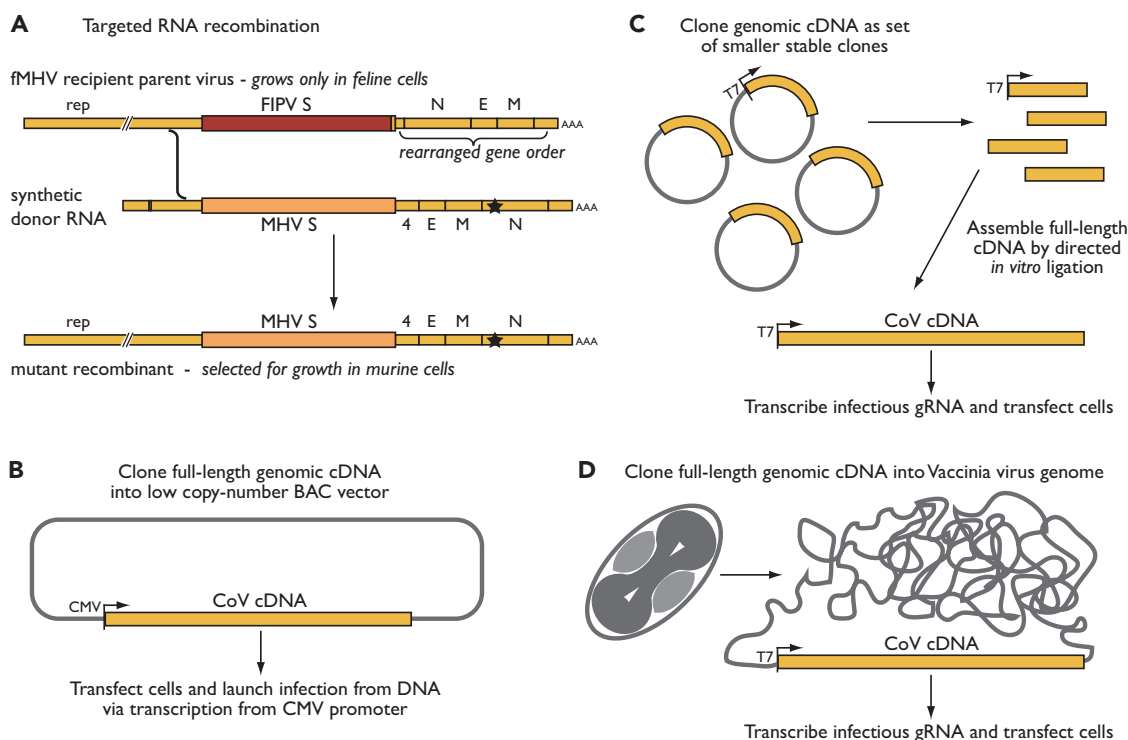

FIGURE 28.5. Methods for coronavirus reverse genetics. **A:** Targeted RNA recombination, which is applicable to the downstream third of the genome, shown here for transduction of a mutation (*star*) into the mouse hepatitis virus *N* gene. **B–D:** Three schemes developed for complete reverse genetics, based on stable production of full-length genomic complementary DNAs.

transcribed *in vivo* by fowlpox-encoded T7 RNA polymerase.⁵⁸ Collectively, these systems developed for complete reverse genetics provide an important pathway toward unraveling the complexities of the coronavirus replicase.

CORONAVIRUS REPLICATION

Virion Attachment to Host Cells

Coronavirus infections are initiated by the binding of virions to cellular receptors (Fig. 28.6). There then follows a series of events culminating in the delivery of the nucleocapsid to the cytoplasm, where the viral genome becomes available for translation. Individual coronaviruses usually infect only one or a few closely related hosts. The interaction between the viral S protein and its cognate receptor constitutes the principal determinant governing coronavirus host species range and tissue tropism. This has been most convincingly shown in two ways. First, the expression of a particular receptor in nonpermissive cells of a heterologous species renders those cells permissive for the corresponding coronavirus.^{127,146,330,331,399,567,639} Second, the engineered replacement of the S protein ectodomain changes the host cell species specificity or tissue tropism of a coronavirus in a predictable fashion.^{207,292,410,453,495} The amino-terminal, more variable half of the spike protein, S1, is the part that binds to receptor. Binding leads to conformational changes that result in fusion between virion and cell membranes, medi-

ated by the more conserved half of the spike protein, S2. The region of S1 that contacts the receptor—the receptor-binding domain (RBD)—varies among different coronaviruses (see Fig. 28.3). For MHV, the RBD maps to the N-terminal section of S1.^{290,554} By contrast, RBDs for SARS-CoV,^{614,625} HCoV-NL63,³³⁷ transmissible gastroenteritis virus (TGEV),¹⁸⁸ and HCoV-229E³⁴ fall in the middle or C-terminal sections of S1.

The known cellular receptors for alpha- and betacoronaviruses are listed in Table 28.2; to date, no receptors have been identified for gammacoronaviruses. The MHV receptor mCEACAM1 was the first discovered coronavirus receptor (as well as one of the first receptors defined for *any* virus).^{606,607} That this molecule is the only biologically relevant receptor for MHV was made clear by the demonstration that homozygous *Ceacam1*^{-/-} knockout mice are totally resistant to infection by high doses of MHV.²¹⁵ CEACAM1 is a member of the carcinoembryonic antigen (CEA) family within the immunoglobulin (Ig) superfamily and, in its full-length form, contains four Ig-like domains.¹⁴⁶ A diversity of two- and four-Ig domain isoforms is generated by multiple alleles and alternative splicing variants of *Ceacam1*.^{97,145,147,422,423,641} The wide range of pathogenicity of MHV in mice is thought to be strongly affected by the interactions of S proteins of different virus strains with the array of receptor isoforms that are expressed in mice of different genetic backgrounds. Although their S proteins are phylogenetically very close to that of MHV, the betacoronaviruses BCoV and HCoV-OC43 do not use CEACAMs to infect their

FIGURE 28.6. Overview of coronavirus replication (see text for details).

TGEV, transmissible gastroenteritis virus; pAPN, porcine aminopeptidase N; PRCoV, porcine respiratory coronavirus; PEDV, porcine epidemic diarrhea virus; FeCoV, feline coronavirus; fAPN, feline aminopeptidase N; FIPV, feline infectious peritonitis virus; CCoV, canine coronavirus; cAPN, canine aminopeptidase N; HCoV, human coronavirus; hAPN, human aminopeptidase N; ACE2, angiotensin-converting enzyme 2; MHV, mouse hepatitis virus; mCEACAM1, murine carcinoembryonic antigen–related adhesion molecule 1; BCoV, bovine coronavirus; SARS-CoV, severe acute respiratory syndrome coronavirus.

^aMammalian aminopeptidase N is also known as CD13.

^bAlthough the receptor for FeCoV I remains to be identified, the lectin fDC-SIGN serves as a coreceptor for both FeCoV I and FeCoV II.⁴⁷¹

^cThe related molecule mCEACAM2 functions weakly as an MHV receptor in tissue culture; however, it is not an alternate receptor in the mouse host *in vivo*.²¹⁵

^dHuman CD209L (L-SIGN), a lectin family member, can also act as a receptor for SARS-CoV but with much lower efficiency than ACE2²⁵⁴; a related lectin, DC-SIGN, can serve as a coreceptor.^{376,635}

hosts; rather, the only currently known attachment factor for these viruses is N-acetyl-9-*O*-acetylneuraminic acid.^{291,504} The recently solved structure of the MHV RBD complexed with mCEACAM1 has allowed the identification of key residues at the S protein–receptor interface.⁴⁴³ Coupled with mutational analysis, this structure reveals why the S proteins of BCoV and HCoV-OC43 cannot bind the MHV receptor and, conversely, why MHV does not bind to bovine or human CEACAMs.

Many alphacoronaviruses use aminopeptidase N (APN) of their respective host species as a receptor (see Table 28.2).^{127,567,639} APN (also called CD13) is a cell-surface, zinc-binding protease that is resident in respiratory and enteric epithelia and in neural tissue. The APN molecule is a heavily glycosylated homodimer. Mutational and inhibitor studies have shown that its enzymatic activity is not required for viral attachment and entry.¹²⁶ In general, the receptor activities of APN homologs are not interchangeable among species^{126,281}; however, feline aminopeptidase N (fAPN) can serve as a receptor not only for FIPV but also for canine coronavirus (CCoV), TGEV, and HCoV-229E.⁵⁶⁷ This circumstance has been exploited for the construction of chimeric APN molecules to map the basis for receptor recognition. Such studies have found

three small, linearly discontinuous determinants in APN that govern the species specificity of this subgroup of alphacoronaviruses.^{29,214,280,569}

The receptor for SARS-CoV—angiotensin-converting enzyme 2 (ACE2)—was discovered with notable rapidity following the isolation of the virus.³³¹ ACE2 is a cell-surface, zinc-binding carboxypeptidase involved in regulation of cardiac function and blood pressure. It is expressed in epithelial cells of the lung and the small intestine, which are the primary targets of SARS-CoV, as well as in heart, kidney, and other tissues.²⁰⁹ As with APN, the receptor role of ACE2 appears to be independent of its enzymatic activity. Although the SARS-CoV S protein binds to the catalytic domain of ACE2, active-site mutation or chemical inhibition does not detectably affect the ability of ACE2 to associate with S protein or to promote syncytia formation.^{331,333,398} The crystal structure of the SARS-CoV S protein RBD in complex with ACE2 shows the RBD cradling one lobe of the claw-like catalytic domain of its receptor.³²⁵ Remarkably, ACE2 also serves as the receptor for the alphacoronavirus HCoV-NL63,²¹⁹ and the corresponding structural complex for that virus reveals that the HCoV-NL63 RBD and the SARS-CoV RBD bind to the same motifs.⁶²⁴ Because the SARS-CoV and HCoV-NL63 RBDs have neither sequence nor structural homology, this finding strongly supports the notion that they have independently evolved to bind to the same hotspot on the ACE2 surface.^{623,624} Analyses of the SARS-CoV RBD–ACE2 interface have additionally demonstrated the structural basis for the final jump of SARS-CoV from palm civets to human hosts (see the Epidemiology section). These studies found that merely four critical residues constitute the major species barrier between the civet and human ACE2 molecules, and that mutation of only two key RBD residues was sufficient for civet SARS-CoV S protein to gain the ability to productively bind human ACE2.^{323,333}

Viral Entry and Uncoating

The entry of virions into cells results from large-scale rearrangements of the S protein that lead to the fusion of viral and cellular membranes.⁴¹ These rearrangements are triggered by some combination of receptor binding, proteolytic cleavage of S, and exposure to acidic pH. The S proteins of many coronaviruses are uncleaved in mature virions and require an encounter with a protease at the entry step of infection to separate the receptor-binding and fusion components of the spike. The details of proteolytic activation are still incompletely understood but have been best studied for SARS-CoV. In the cell types in which this virus is most commonly grown in tissue culture, viral entry depends on cathepsins, which are acid-activated endosomal proteases. The infectivity of SARS-CoV is thus suppressed by cathepsin inhibitors or by lysosomotropic agents.⁵¹⁷ However, cell-bound SARS-CoV can alternatively be activated by treatment with extracellular proteases, such as trypsin or elastase. This route of activation greatly enhances the infectivity of SARS-CoV and allows the virus to enter from the cell surface, thereby rendering the infection insensitive to lysosomotropic agents.³⁸³ The same pattern of proteolytic activation—cathepsin-dependence and its circumvention by exogenously added protease—is observed with a particular strain of MHV (MHV-2) that is unique in having an uncleaved S protein.⁴⁶⁴

The site of cleavage of receptor-bound SARS-CoV S protein by cathepsin or by exogenous trypsin differs from that of the S1-S2 cleavage, which occurs in other coronaviruses upon exit from cells. Cleavage at entry takes place at a locus (S2') within the S2 half of the molecule, immediately upstream of the putative fusion peptide²⁸ (see Fig. 28.3). It is not yet clear if cleavage at analogous S2' sites is the pattern for all coronavirus S proteins; however, the emerging pattern is that proteolytic activation of S protein is required for infectivity and that coronaviruses have evolved in different ways to ensure that this occurs.⁴¹ Recent studies provide evidence that for the SARS-CoV S protein, the most biologically relevant protease may be TMPRSS2.^{187,382,514} This transmembrane serine protease, which is expressed in pneumocytes, co-localizes with and binds to ACE2. In cells expressing TMPRSS2, SARS-CoV enters at the cell surface and is insensitive to cathepsin inhibitors and lysosomotropic agents.

Just as the mechanism of S protein proteolytic activation is variable, so too is its location. Some coronaviruses, such as most strains of MHV, fuse with the plasma membrane,^{547,601} whereas others, such as TGEV,²¹² HCoV-229E,⁴²¹ and SARS-CoV,⁵¹⁷ can enter cells through receptor-mediated endocytosis and then fuse with the membranes of acidified endosomes. The boundary between these two modes of entry may easily shift. For one strain of MHV (MHV-4), as few as three amino acid changes in the heptad repeat region of S2 switches the virus from plasma membrane fusion to acid pH-dependent fusion.¹⁸⁰ It remains unresolved whether acidic pH, *per se*, is required for S protein conformational changes^{90,154,324} or whether this reflects the requirements for activation of endosomal proteases during infection of some types of cells.⁵¹⁷

The coronavirus S protein is a class I viral fusion protein with domains functionally similar to those of the fusion proteins of phylogenetically distant RNA viruses, such as influenza virus, human immunodeficiency virus (HIV), and Ebola virus, but on a much larger scale.^{41,42} As in those other viral fusion proteins, the coronavirus S2 moiety contains two separated heptad repeats—HR1 and HR2—with a fusion peptide upstream of HR1 and the transmembrane domain immediately downstream of HR2 (see Fig. 28.3). The exact assignment of the fusion peptide is not agreed upon, however.^{41,367,450} Receptor-mediated conformational changes in S1, and the dissociation of S1 from S2, are thought to initiate major rearrangements in the remaining S2 trimer that proceed through multiple intermediate states.^{133,324} These rearrangements ultimately expose the fusion peptide, which interacts with the host cellular membrane, and the two heptad repeats in each monomer are brought together to form an antiparallel, six-helix bundle. The six-helix bundle is an extremely stable, rod-like complex, the biophysical properties of which have been extensively studied.^{40,42,242,348,568} Highly similar crystallographic structures have been solved for the six-helix complexes from both the MHV S protein⁶²⁹ and the SARS-CoV S protein.^{144,552,630} These show the three HR1 helices forming a central, coiled-coil core some two to three times larger than its counterparts in other viruses. Arrayed around this, the three shorter HR2 helices, in an antiparallel orientation, pack into the grooves between the HR1 monomers via hydrophobic interactions. The outcome of the formation of the six-helix bundle is the juxtaposition of the viral and cellular membranes in sufficient proximity to allow mixing of their lipid bilayers and the deposition of the contents of the virion into the cytoplasm.

Expression of the Replicase-Transcriptase Complex

Following delivery of the viral nucleocapsid to the cytoplasm, the next event is the translation of the *replicase* gene from the genomic RNA. This gene consists of two large ORFs—rep 1a and rep 1b—that share a small region of overlap (see Fig. 28.4). Translation of the entire replicase depends on a mechanism called *ribosomal frameshifting*, whereby, with a fixed probability, a translating ribosome shifts one nucleotide in the –1 direction, from the rep 1a reading frame into the rep 1b reading frame.³⁷⁸ This repositioning is programmed by two RNA elements (Fig. 28.7A), embedded near the region of overlap, that were discovered in studies of IBV.^{46,47} The first element is the 5'-UUUAAAC-3' heptanucleotide slippery sequence, which is identical for all known coronaviruses and has apparently been selected as optimal for its role.^{48,457} The second element, located a short distance downstream of the slippery sequence, is an extensively characterized RNA pseudoknot structure.^{49,405} This latter component was initially thought to be a classic two-stem (H-type) pseudoknot; however, recent analyses of SARS-CoV frameshifting support a more elaborate structure that includes a third stem loop within pseudoknot loop 2.^{20,141,456}

The two elements act together to produce the coterminal polypeptide products pp1a and pp1ab. During most rounds of translation, the elongating ribosome unwinds the pseudoknot and translation terminates at the rep 1a stop codon, yielding the smaller product, pp1a. Some fraction of the time, however, the pseudoknot blocks the mRNA entrance channel of the ribosome.^{213,403,528} The consequent pause required for the ribosome to melt out the mRNA structure allows the simultaneous slippage of the P and A site transfer RNAs (tRNAs) into the rep 1b reading frame. This results in the synthesis of pp1ab when elongation resumes.^{20,47} Studies of reporter gene expression suggest that the incidence of coronaviral ribosomal frameshifting is as high as 25% to 30%; however, the *in vivo* frequency in infected cells remains to be quantitated. It is thought that the role of programmed frameshifting is to provide a fixed ratio of translation products for assembly into a macromolecular complex.⁴⁵⁷ It is also possible that frameshifting forestalls expression of the enzymatic products of rep 1b until the products of rep 1a have prepared a suitable environment for RNA synthesis.

Polypeptides pp1a (440–500 kDa) and pp1ab (740–810 kDa) are autoproteolytically processed into mature products that are designated nsp1 to nsp16 (except for the gammacoronaviruses, which do not have a counterpart of nsp1). From work begun with early studies of MHV^{134,135,525} complete processing schemes have now been solved for replicases of multiple coronaviruses representing all three genera^{659,661} (see Fig. 28.7B). Processing also generates many long-lived partial proteolytic products, which may have functional importance. There are two types of polypeptide cleavage activity.^{17,358} One or two papain-like proteases (PL^{pro}), which are situated in nsp3, carry out the relatively specialized separation of nsp1, nsp2, and nsp3. The main protease (M^{pro})—nsp5—performs the remaining 11 cleavage events. M^{pro} is often designated the 3C-like protease (3CL^{pro}) to point out its distant relationship to the 3C proteins of picornaviruses. Several crystal structures have been determined for PL^{pro} and M^{pro} of SARS-CoV and other

FIGURE 28.7. Coronavirus replicase gene and protein products. **A:** Ribosomal frameshifting elements of the SARS-CoV replicase gene. Pseudoknot stems are indicated as s1, s2, and s3. **B:** Polyprotein pp1a and pp1ab processing scheme for alpha- and betacoronaviruses. The gammacoronavirus processing scheme is identical, except for the absence of nsp1. Known functions and properties of nsp1 through nsp16 are listed; nsp11 is an oligopeptide generated when ribosomal frameshifting does not occur. Transmembrane domains in nsp3, nsp4, and nsp6 are indicated by red vertical lines. The nsp3 schematic shown is for SARS-CoV⁴¹⁴; some modules differ in other coronaviruses. **C:** The RNA packaging signal located in the nsp15-encoding region of the MHV genome.⁸¹ This element is found only in a subset of the betacoronaviruses (MHV, betacoronavirus 1, and HCoV-HKU1); repeat units are boxed. SARS-CoV, severe acute respiratory syndrome coronavirus; MHV, mouse hepatitis virus; HCoV, human coronavirus.

coronaviruses,^{9,469,612,631} and these enzymes present attractive targets for antiviral drug design.^{468,633,634}

The processed nsps assemble to form the coronavirus replicase, which is also referred to as the replicase-transcriptase complex (RTC).⁶⁶⁰ The challenge of defining the roles of the many nsp components of the RTC was initially addressed by foundational studies in bioinformatics,^{196,317} which is a discipline that continues to inform the analysis of this intricate molecular machinery.^{414,521} Besides PL^{pro} and M^{pro}, the products of rep 1a contain several activities that establish cellular conditions favorable for infection. Some of these are directly linked to RNA synthesis. Others are nonessential for viral replication in tissue culture; however, they can have major effects on virus–host interactions (see the Immune Response and Viral Evasion

of the Immune Response section). The very first polyprotein product—nsp1—exhibits a broad repertoire of antagonistic activities that selectively inhibit host protein synthesis and IFN signaling.^{230,258,259} By contrast, nsp2 is completely expendable and, as yet, has no demonstrated function.¹⁹⁹

Nsp3 is by far the largest of the RTC proteins. It consists of a concatenation of individual structural modules that are arranged as globular domains separated by flexibly disordered linkers⁴¹⁴ (see Fig. 28.7B). At the amino terminus of nsp3 are ubiquitin-like (Ubl1) and acidic (Ac) domains⁵⁰⁶ that interact with the SR region of the N protein.²³⁷ It is proposed that this interaction tethers the genome to the assembling RTC to allow formation of the initiation complex for RNA synthesis. As mentioned earlier, located within nsp3 are one (in SARS-CoV and

gammacoronaviruses) or two PL^{pro} modules (in most other coronaviruses). In addition to protease activity, PL^{pro} domains possess deubiquitinase activity,^{341,469,612} which forms another part of the viral arsenal that counters host innate immunity.^{136,174} A highly conserved domain of nsp3 has adenosine diphosphate-ribose-1"-phosphatase (ADRP) and poly(adenosine diphosphate [ADP]-ribose)-binding activities,^{152,494} which, although nonessential for replication, help confer resistance to host defenses.^{158,297} At the C-terminus of nsp3 is a conserved region, designated the Y domain, containing three metal-binding clusters of cysteine and histidine residues.^{414,662} The potential functions of other domains of nsp3 (NAB, G2M, SUD),^{73,414,507,521} which appear only in various subsets of coronaviruses, remain to be elucidated.

Notably, the rep 1a products nsp3, nsp4, and nsp6 each contain multiple transmembrane helices that anchor the RTC to intracellular membranes.^{262,424} These proteins also appear to be responsible for remodeling cellular membranes to form structures that are dedicated to viral RNA synthesis.^{92,178} Recent cryo-electron tomographic imaging has revealed an extensive network of convoluted membranes, double-membrane vesicles (DMVs), and vesicle packets, all continuous with the ER, induced by coronavirus infection²⁷⁷ (Fig. 28.8). Anchorage and compartmentalization of the RTC are thought to provide a scaffold for recruitment of soluble nsps, to offer protection from ribonucleases, and to sequester double-stranded viral

RNA intermediates that might activate host innate immunity (see the Immune Response and Viral Evasion of the Immune Response section).

The most C-terminal rep 1a products are nsp7 through nsp10, a cluster of essential small proteins.¹³¹ Structural studies have revealed that two of these—nsp7 and nsp8—form a hexadecameric supercomplex with a central channel large enough to accommodate double-stranded RNA.⁶⁵¹ This formidable assembly has thus been proposed to act as a processivity clamp for the RNA polymerase. Nsp9 is a single-stranded RNA-binding protein,^{151,553} and nsp10 defines a novel structural class of zinc finger proteins.^{257,548}

The processed products encoded by rep 1b contain several well-studied enzymatic activities, including many that are common to all positive-strand RNA viruses. Most prominent in this latter class is the coronavirus RNA-dependent RNA polymerase (RdRp), which is contained in nsp12. Sequence alignment and homology modeling indicate that nsp12 has the fingers, palm, and thumb domains characteristic of several viral RdRps and reverse transcriptases⁶²⁸; however, to date, this protein has proven refractory to structural determination. Additionally, nsp12 has an unusually large NTD, at least part of which mediates targeting to the RTC.⁵² Coronavirus RdRp activity, *in vitro*, is primer dependent.^{83,560} Remarkably, a second RdRp activity resides in nsp8 and is capable of synthesizing short RNA oligomers.²⁴⁰ Nsp8 is thus the optimal candidate for the requisite primase. Another enzyme crucial to RNA synthesis is the helicase of nsp13. This activity unwinds RNA duplexes with a 5' to 3' polarity, suggesting that its role is to prepare the template ahead of the RdRp.^{247,248} The nsp13 helicase has an amino-terminal zinc finger domain that is found only in nidoviruses.⁵¹⁰

Like many RNA viruses, coronaviruses contain machinery capable of catalyzing multiple steps of the pathway for synthesis of the 5'-terminal cap structure of mRNA. An RNA 5'-triphosphatase, which would be required for the first step, is yet another property of nsp13.^{247,248} Intriguingly, a guanylyltransferase has thus far not been identified among the nsps. The nsp14 C-terminus and nsp16, respectively, harbor N7-methyltransferase and 2'-O-methyltransferase activities.^{82,123} These enzymes operate in an obligatory sequential manner, with guanosine-N7 methylation preceding ribose-2'-O methylation. Activation of the nsp16 methyltransferase requires nsp10 as a cofactor, and the crystal structure of a heterodimer of these two proteins suggests that nsp10 serves as a platform to stabilize nsp16.^{43,122} Genetic evidence also implicates nsp10 as a regulator of polyprotein processing by the nsp5 M^{pro}.¹³⁸

Finally, there are two rep 1b-encoded activities that are not found outside the order *Nidovirales*^{194,521}; surprisingly, both are ribonucleases. The first is an endonuclease, designated NendoU, which resides in nsp15. NendoU hydrolyzes both single- and double-stranded RNA and specifically cleaves downstream of uridylate residues, producing 2'-3' cyclic phosphates.^{33,246} Although it bears homology to XendoU, an enzyme involved in small nucleolar RNA (snoRNA) processing, the potential role of NendoU in coronavirus RNA synthesis is not clear. It is also unresolved whether NendoU is essential or if lethal mutations constructed in nsp15 affect some other function of that protein.^{246,260} The second activity is ExoN, a 3'-5' exonuclease that is associated with the amino-terminal portion

FIGURE 28.8. Membranous compartments for RNA replication and transcription induced by coronavirus infection. Shown is a cryo-electron tomographic reconstruction of the network of intracellular membrane rearrangements found in SARS-CoV-infected Vero cells. There are three types of structures: convoluted membranes (CM), which are the major sites of nsp accumulation; double-membrane vesicles (DMV), which appear to be the sites of active RNA synthesis; and vesicle packets (VP), which are formed by the merger of DMV. (From Knoops K, Kikkert M, Worm SH, et al. SARS-coronavirus replication is supported by a reticulovesicular network of modified endoplasmic reticulum. *PLoS Biol* 2008;6:e226.)

of nsp14.³⁹⁵ This enzyme is not essential for viral replication; however, nsp14 mutants have a greatly enhanced mutation rate, supporting the notion that ExoN provides a proofreading function for the coronavirus RdRp.^{149,150} Such a corrective activity may be critical for maintenance of the stability of the exceptionally large coronavirus genome.

Viral RNA Synthesis

Expression and assembly of the RTC sets the stage for viral RNA synthesis (see Fig. 28.6), a process resulting in the replication of genomic RNA and the transcription of multiple subgenomic RNAs (sgRNAs).^{299,433,577} The latter species serve as mRNAs for the genes downstream of the *replicase* gene. Each sgRNA consists of a leader RNA of 70 to 100 nucleotides, which is identical to the 5' end of the genome, joined to a body RNA, which is identical to a segment of the 3' end of the genome. The fusion of the leader RNA to body RNAs occurs at short motifs—TRSs—examples of which are listed in

Figure 28.9. Like the genome, the sgRNAs have 5' caps and 3' polyadenylate tails. Together, these transcripts form a 3'-nested set—the single most distinctive feature of the order *Nidovirales*.^{157,194} Synthesis of both genomic RNA and sgRNAs proceeds through negative-strand intermediates.^{24,509} The negative sense RNAs, which possess 5' oligouridylylate tracts²²⁰ and 3' antileaders,⁵⁰⁸ are roughly a tenth to a hundredth as abundant as their positive sense counterparts.

At their 5' and 3' termini, coronavirus genomes contain *cis*-acting RNA elements that allow their selective recognition as templates for the RTC and play essential roles in RNA synthesis (see Fig. 28.9). The initial localization of these elements was carried out in studies of defective interfering (DI) RNAs, which are extensively deleted genomic variants that propagate by competing for the viral RNA synthesis machinery.^{69,371,393,445,575} Manipulations of natural and artificially constructed DI RNAs, evaluated by transfection into helper-virus-infected cells, made possible the mapping of sequences

FIGURE 28.9. Coronavirus RNA synthesis. Shown are a schematic of MHV genomic RNA and the nested set of transcribed subgenomic RNA species that are a defining feature of the order *Nidovirales*. The leader and body copies of the TRS (TRS-L and TRS-B, respectively) are denoted by green boxes. At the left are listed examples of consensus TRSs that have been experimentally confirmed^{462,463,531,562}; the inferred TRSs of other coronaviruses are identical or highly similar to these. Expanded regions above the genome depict *cis*-acting RNA structures at the genome termini. The structures shown are those characterized for MHV.^{190,202,346,667} Homologous structures exist in the BCoV^{53,622} and SARS-CoV genomes,^{192,261} and counterparts of some of these elements appear in other coronaviruses.^{80,107,605} The 5' expanded region represents the 210-nt 5' UTR and the first 140 nt of the *rep 1a* gene; the elements shown are SLs I through VI, numbered as originally described for BCoV.^{53,202} TRS-L is denoted in green in SL II; the start codon of *rep 1a* is boxed in SL IV. The 3' expanded region represents the 301-nt 3' UTR. The elements shown are the bulged stem loop (BSL), the pseudoknot (PK), the hypervariable region (HVR), and the conserved coronavirus octanucleotide motif (*oct*); the stop codon for the upstream *N* gene is boxed. MHV, mouse hepatitis virus; TRS, transcription-regulating sequence; BCoV, bovine coronavirus; SARS-CoV, severe acute respiratory syndrome coronavirus; UTR, untranslated region; nt, nucleotide; SL, stem loop.

that are critical for the replication and transcription of DI RNA and, presumably, also for genomic RNA.^{45,379} More recently, *cis*-acting RNA elements have been dissected through reverse genetics of the intact viral genome, complemented by *in vitro* biochemical and structural analyses. The most completely characterized structures and sequences are those of the betacoronaviruses MHV, BCoV, and SARS-CoV (see Fig. 28.9).

At the 5' end of the genome, the elements that participate in viral RNA synthesis extend well beyond the 5' UTR into the replicase coding region, making up a set of seven stem loops.^{53,202,346,467} One of these displays the leader copy of the TRS (TRS-L) in its loop, and another sequesters the start codon of the *rep 1a* gene within its stem. Many, but not all, of these defined structures can be exchanged among the genomes of different betacoronaviruses.^{202,261} Significantly, functional analyses have shown that either the stability^{202,346} or the instability³²⁹ of a given RNA stem can be critical for viral fitness, suggesting that these structures operate in a dynamic manner during RNA synthesis.

At the 3' end of the genome, *cis*-acting RNA elements are confined entirely to the 3' UTR¹⁹⁰ and are functionally interchangeable among the betacoronaviruses.^{192,228,622} These elements consist of a bulged stem loop²²⁸ and an adjacent pseudoknot⁶⁰⁵ that have each been demonstrated to be essential for viral replication. Further downstream is a hypervariable region, which is completely dispensable for viral replication but yet harbors 5'-GGAAGAGC-3', an octanucleotide motif that is universally conserved in the coronaviruses.^{191,347} Notably, the bulged stem loop and the pseudoknot partially overlap, and they therefore can not fold up simultaneously. The two structures are thus thought to constitute a molecular switch between different steps of RNA synthesis.^{190,227} In addition, the first loop of the pseudoknot forms a duplex with the extreme 3' end of the genome and genetically interacts with the RTC subunits nsp8 and nsp9.⁶⁶⁷ On this basis, a mechanism has been proposed in which alternate RNA conformations of the 3' UTR facilitate the transition between initiation of negative-strand RNA synthesis by the nsp8 primase and elongation by the nsp12 RdRp. However, this scheme does not yet incorporate potential cross talk between the 5' and 3' ends of the genome,³²⁹ and much remains to be learned about how *cis*-acting RNA elements are recognized by, and cooperate with, the RTC.

A central issue in coronavirus RNA synthesis is how the leader RNA becomes attached to the body segments of the sgRNAs. It became clear from early work that transcription involves a discontinuous process. Ultraviolet (UV) transcriptional mapping demonstrated that sgRNAs are not processed from a genome-length precursor,^{250,537} and mixed infections with two different strains of MHV showed that leader RNAs could reassort between separate sgRNA body segments.³⁷² It was also clearly established by DI RNA studies, and later confirmed by genomic reverse genetics,^{527,664} that the TRSs play key roles in sgRNA formation. The efficiency of fusion at an individual body TRS (TRS-B) is, in part, governed by how closely it conforms to the leader TRS (TRS-L).^{217,369,576} Nonetheless, factors such as the local sequence context of the TRS and the position of the TRS relative to the 3' end of the genome also profoundly influence transcription levels.^{286,429,580}

Originally, the leader-to-body fusion event was envisioned to occur by a leader-primed mechanism during positive-strand RNA synthesis.^{298,300,652} However, there is now broad,

although not universal, agreement that fusion takes place through discontinuous extension of negative-strand RNA synthesis.^{433,496,498,664} In this model, both genomic and subgenomic negative-strand RNAs are initiated by the RTC at the 3' end of the (positive-strand) genome template (Fig. 28.10). A pause in RNA synthesis occurs when the RdRp crosses a TRS-B. At this point, the RdRp may continue to elongate the growing negative strand. Alternatively, it may switch to the leader at the 5' end of the genome template, guided by the complementarity between the 3' end of the nascent negative strand and the TRS-L of the genome. The resulting negative-strand sgRNA, in partial duplex with positive-strand gRNA, then serves as the template for synthesis of multiple copies of the corresponding positive-strand sgRNA.

Leader-to-body fusion during negative-strand synthesis is amply supported by accumulated experimental results with coronaviruses and the closely related arteriviruses. First, as necessitated by the model, negative-strand sgRNAs contain antileaders at their 3' ends.⁵⁰⁸ Second, in infected cells, there exist transcription intermediates containing negative-strand sgRNAs in association with the genome. These complexes actively participate in transcription^{24,497} and can be biochemically separated from replication intermediates containing genome-length negative-strand RNAs.⁵⁰⁰ Finally, as would be predicted for discontinuous negative-strand synthesis, engineered (or naturally occurring) variant nucleotides incorporated into the TRS-B, rather than the TRS-L, end up in the leader-body junction of the resulting sgRNA.^{238,434,579,664} There remains, however, considerable further work to be done to elucidate the details of the model.^{433,498} It is not clear how the transcribing RdRp might continuously monitor the ability of its nascent product to base pair to the TRS-L. Additionally, the synthesis of genome-length negative strands would require the RdRp to bypass all of the TRS-B sites in the genome template. This may come about through a stochastic process, or it may be actively promoted by some RTC component under certain conditions. These and other questions will need to be addressed, possibly with the aid of a robust *in vitro* viral RNA synthesizing system.⁵⁷⁸ Such a system may also be decisive in assessing the potential roles of host factors in transcription and replication. Several cellular proteins, including hnRNP A1,^{327,512,513} polypyrimidine tract-binding protein,^{326,526} mitochondrial aconitase,⁴⁰⁴ and polyadenylate-binding protein,⁵³² have been proposed to take part in coronavirus RNA synthesis, mainly based on their ability to bind *in vitro* to genomic RNA segments. Because many putative host factors also play critical or essential roles in normal cellular functions, it has been difficult to convincingly demonstrate their specific involvement in viral processes. As yet, only a single candidate host factor has been shown to be required for *in vitro* viral RNA synthesis.⁵⁷⁸

In addition to its central role in sgRNA formation, template switching is also at the heart of RNA recombination—another prominent feature of coronavirus RNA synthesis. Significant rates of both homologous and nonhomologous RNA recombination have been found among selected and unselected markers during the course of infection.^{266,267,268,370} It is presumed, but remains to be formally demonstrated, that coronavirus RNA recombination results from a copy-choice mechanism, as originally established for poliovirus.²⁷³ In MHV, recombination takes place at an estimated frequency of 1% per 1.3 kb (almost 25% over the entire genome)—the

FIGURE 28.10. Coronavirus transcription through discontinuous extension of negative-strand RNA synthesis.^{496,498,664} **A, B:** Negative-strand sgRNA synthesis initiates at the 3' end of the positive-strand genomic RNA template. In the version of the model shown here, the genomic template loops out in such a way as to allow a component of the RTC to constantly monitor the potential complementarity of the 3' end of the nascent negative-strand RNA with the TRS-L. **C:** Transcription pauses at a TRS-B. At this point, elongation may resume, thereby bypassing the TRS-B. **D:** Alternatively, the nascent negative strand may switch templates, binding to the TRS-L. **E:** Resumption of elongation results in completion of synthesis of an antileader-containing negative-strand sgRNA. **F:** The resulting complex of genome and negative-strand sgRNA acts as template for the synthesis of multiple copies of the corresponding positive-strand sgRNA. sgRNA, subgenomic RNA; RTC, replicase-transcriptase complex; TRS, transcription-regulating sequence. (Adapted from Zúñiga S, Sola I, Alonso S, et al. Sequence motifs involved in the regulation of discontinuous coronavirus subgenomic RNA synthesis. *J Virol* 2004;78:980–994.)

highest rate observed for any RNA virus.²² On a fine scale, the sites of crossover are random,¹⁹ although selective pressures can generate the appearance of local clustering of recombinational hot spots.¹⁸ This facility for RdRp strand switching may make a major contribution to the ability of the huge coronavirus genome to evolve and to circumvent the accumulation of deleterious mutations. It also serves as the basis for targeted RNA recombination (see the Coronavirus Genetics section).

Assembly and Release of Virions

The immediate outcome of transcription is to enable translation of the proteins that build progeny viruses. The membrane-bound proteins M, S, and E are initially inserted into the ER; from there, they transit to the site of virion assembly, the endoplasmic reticulum–Golgi intermediate compartment (ERGIC).^{275,285,563} Here, nucleocapsids composed of progeny genomes encapsidated by N protein coalesce with the envelope components to form virions, which bud into the ERGIC^{117,222,378} (see Fig. 28.6).

Coronavirus assembly occurs through a network of cooperative interactions, most of which involve M protein. However, despite its central role, M is not assembly competent by itself. Expression of M protein alone does not result in virion-like structures, and M traverses the secretory pathway beyond the budding site, as far as the *trans*-Golgi.^{275,362,363,489} The first

virus-like particle (VLP) systems developed for coronaviruses led to the key finding that co-expression of E protein with M protein is sufficient to yield the formation of particles that are released from cells and appear morphologically identical to coronavirus envelopes.^{37,582} More recently, it has been shown that the additional co-expression of N protein substantially increases the efficiency of VLP formation^{38,519} and can even compensate for mutational defects in M.¹⁵ Other viral structural proteins, in particular S protein, are gathered into virions but are not specifically required for the assembly process. Because virions and VLPs contain very little E protein, this indicates that lateral interactions between M molecules provide the driving force for envelope morphogenesis. Investigations of the ability of M protein mutants to support VLP assembly concluded that M–M interactions occur via multiple contacts throughout the molecule, especially between the transmembrane domains.^{114,120} Recent cryo-electron tomographic reconstructions of whole virions suggest that the M protein forms dimers that are maintained through multiple monomer–monomer contacts, while dimer–dimer interactions occur among the globular endodomains.⁴¹⁵

It remains enigmatic how E protein critically assists M in envelope formation. Like M, E protein by itself moves to a compartment past the ERGIC^{93,100}; however, co-expression or infection somehow secures localization of M and E at the

budding site. Some evidence suggests that E protein promotes assembly by inducing membrane curvature.^{100,166,465} Other work indicates a role for E in maintaining M protein in an assembly-competent state by preventing its nonproductive aggregation—a function that crucially depends on palmitoylation of E.³⁸ Such a chaperone-like role would be consistent with demonstrations that diverse heterologous E proteins, and even truncated versions of M protein, can functionally replace E protein in MHV.^{293,294} Finally, there are reports that point to a need for E protein to facilitate the release of assembled virions from infected cells.^{364,427} These roles are not mutually exclusive, and some recent studies have begun to assign individual functions to various regions of the E molecule. The C-terminal endodomain of the IBV E protein governs Golgi localization^{100,101} and when linked to a heterologous transmembrane domain can support VLP and virion assembly.^{364,491} Conversely, the transmembrane domain of E alters the host secretory pathway in a way that promotes virus release.⁴⁹¹ This latter effect is potentially a consequence of the putative ion channel properties of the E transmembrane domain^{449,609,610,638}; however, it is unresolved whether native E protein acts as an ion channel at intracellular membranes *in vivo*.⁴²⁰

The dispensability of S protein for VLP formation is consistent with earlier observations that spikeless (noninfectious) virions were formed by infected cells treated with the glycosylation inhibitor tunicamycin^{224,487} or by cells infected with particular S mutants.^{360,474} S protein thus appears to play a passive role in assembly; however, during its passage through the secretory pathway, it is captured by M protein for virion incorporation.^{387,426} For some S proteins, localization at or near the budding compartment is abetted by targeting signals contained in the endodomain.^{353,386,611} The S endodomain is also the region of the protein that interacts with M during assembly.^{39,636} Conversely, the ability of M protein to interact with S maps to a locus close to the C-terminus of the M endodomain¹¹⁸ (see Fig. 28.3).

Virion assembly is completed by condensation of the nucleocapsid with the envelope components. This is brought about principally by N and M protein interactions, which have been mapped to domain 3 of N^{236,585} and the extreme C-terminus of the M endodomain^{162,295} (see Fig. 28.3). These interacting regions likely account for the thread-like connections that have been visualized between the M protein endodomain and the nucleocapsid in virion reconstructions.^{21,415} Nucleocapsid formation is presumed to be concomitant with genome replication; however, the details of how the nucleocapsid traffics to the budding compartment are not known. It is also not well understood how coronaviruses selectively package genomic RNA from among the many positive- and negative-strand viral RNA species that are synthesized during infection. DI RNA analyses have mapped the genomic packaging signal of MHV to a small span of RNA sequence embedded in the region of the *replicase* gene that encodes nsp15^{169,373,575} (see Fig. 28.7C). Highly homologous structures exist in the genomes of BCoV and HCoV-HKU1.^{81,96} However, for most coronaviruses, including SARS-CoV,²⁵⁶ packaging signals are clearly not found at the same locus, and the relevant structures for these viruses may occur at a large distance, near the 5' ends of their respective genomes.^{80,161} The mechanism by which the MHV packaging signal operates is undetermined. Some studies have shown that it is specifically bound by N protein,^{96,396} although

other work demonstrates that M protein, in the absence of N, acts as the discriminatory factor for packaging signal recognition.^{406,409}

Following assembly and budding, progeny virions are exported from infected cells by transport to the plasma membrane in smooth-walled vesicles and are released by exocytosis. It remains to be more clearly defined whether coronaviruses follow the constitutive pathway for post-Golgi transport of large cargo or, alternatively, if specialized cellular machinery must be diverted for their exit.²²² For some coronaviruses, but not others, a fraction of S protein that has not been assembled into virions transits to the plasma membrane, where it can mediate fusion between infected cells and adjacent, uninfected cells. This leads to the formation of large, multinucleate syncytia, enabling the spread of infection by a means not subject to neutralization by antibody. For MHV, cell–cell fusion depends on S1–S2 cleavage carried out by a furin-like protease late in infection.¹¹⁹ However, this form of proteolytic activation of S does not appear to affect virus–cell fusion that occurs at the initiation of infection. Similarly, the SARS-CoV S protein has different proteolytic requirements for cell–cell and virus–cell fusion.^{168,516} On the opposite side of the membrane from the cleaved ectodomain, the cysteine-rich region of the S protein endodomain also plays a critical role in cell–cell fusion^{36,68,636}; specifically, this has been shown to depend on the palmitoylation of a subset of endodomain cysteine residues.³⁸⁸

PATHOGENESIS AND PATHOLOGY OF CORONAVIRUS INFECTIONS

General Principles

Most coronaviruses spread to susceptible hosts by respiratory or fecal–oral routes of infection, with replication first occurring in epithelial cells (Table 28.3). Some, including HCoV-OC43, HCoV-229E, and porcine respiratory coronavirus (PRCoV), replicate principally in respiratory epithelial cells, where they produce virus and cause local respiratory symptoms. Other coronaviruses, including TGEV, BCoV, porcine hemagglutinating encephalomyelitis virus (PHEV), CCoV, FeCoV, and enteric strains of MHV, infect epithelial cells of the enteric tract. Some of these viruses, such as TGEV, cause diarrhea that is particularly severe, and sometimes fatal, in young animals.⁴⁹² Inapparent enteric infection of adult animals maintains the virus in the population.⁹⁸ In addition to local infection of the respiratory or enteric tracts, several coronaviruses cause severe disease. For example, SARS-CoV spreads from the upper airway to cause a severe lower respiratory tract infection, whereas FIPV spreads systemically to cause a generalized wasting disease in felines.^{439,448} Rat coronavirus strains cause respiratory infection or sialodacryoadenitis owing to infection of the salivary and lacrimal glands⁴⁴⁶ but can also interfere with reproduction by infecting the female urogenital tract.⁵⁷¹ PHEV of swine predominantly causes enteric infection but is also neurotropic.³⁸⁹ Infection spreads to nerves that innervate the stomach of infected piglets and prevents gastric emptying, resulting in vomiting and wasting disease. The ability to cause localized versus systemic disease is mirrored in polarized tissue culture cells. Thus, coronaviruses such as MHV, which can cause systemic disease, enter the apical side of cells and exit the basolateral side, whereas others, such as HCoV-229E, which causes only a localized infection, enter and

TABLE 28.3 Representative Coronaviruses and Associated Diseases

Virus	Host species	Sites of infection	Clinical disease
Alphacoronaviruses			
CCoV	Canine	GI tract	Gastroenteritis
FeCoV	Felidae	GI tract, respiratory	Gastroenteritis
FIPV	Felidae	Systemic disease	Peritonitis, wasting disease
HCoV-229E	Human	Respiratory	Upper respiratory tract infection

exit the cell apically.^{481,482,595} Specific examples are described in more detail later.

Animal Coronavirus Infections

Several coronavirus infections have been extensively studied in their natural hosts. Here, we will focus on murine and feline coronavirus infections.

Mouse Hepatitis Virus

MHV, which until the advent of SARS was the most widely studied coronavirus, causes enteric, hepatic, and neurologic infections of susceptible strains of rodents. Remarkably, closely related strains of MHV, all of which use the same host cell receptor for entry,⁶⁰⁶ infect different organs. Enteric strains, such as MHV-Y and MHV-RI, are a major problem in animal research facilities.⁹⁸ These viruses spread within infected colonies to young, uninfected animals. They do not generally cause symptomatic disease but may subtly impair the host immune response to other pathogens and immunological stimuli.^{98,540} Studies of MHV pathogenesis predominantly use the neurotropic JHM and A59 strains of virus (JHM virus [JHMV] and MHV-A59), in part because they cause a demyelinating encephalomyelitis with similarities to the human disease multiple sclerosis (MS). Originally isolated from a mouse with hind-limb paralysis, JHMV became progressively more virulent on

passage in mice.^{16,75} The most virulent strains of JHMV cause rapidly fatal acute encephalitis with widespread neuronal infection.⁶⁰⁰ Subsequently, most studies have used either attenuated JHMV variants or the mildly neurovirulent MHV-A59 strain for studies of demyelination. Infection with these viruses results in minimal infection of neurons, with oligodendrocytes, microglia, and astrocytes commonly infected.^{167,276,313} Myelin destruction occurs during the process of virus clearance from infected glia.⁵⁹⁴ Initial studies suggested that demyelination resulted from virus-mediated lysis of oligodendrocytes.^{304,600} However, more recent studies show that demyelination is largely immune mediated. In support of this, irradiated mice or congenitally immunodeficient mice (mice with severe combined immunodeficiency [SCID]) or with a disrupted recombination activation gene [*RAG*^{-/-}] do not develop demyelination after infection with JHMV. When these mice, which lack T and B cells, are reconstituted with virus-specific T cells, demyelination rapidly develops^{593,620} (Fig. 28.11). Demyelination is accompanied by infiltration of macrophages and activated microglia into the white matter of the spinal cord.⁶²¹ Little is known, however, about how macrophages and microglia are actually attracted to the spinal cord or about the nature of the signals that cause these cells to phagocytose infected myelin. Both CD4 and CD8 T cells are required for virus clearance from the central nervous system (CNS), with CD8 T cells considered most important in

FIGURE 28.11. Immune-mediated demyelination in mice infected with a neurotropic MHV. RAG1^{-/-} mice, lacking T and B cells, were infected with a neurotropic coronavirus as described.⁶²⁰ Four days later, some mice received adoptively transferred spleen cells from a wild-type C57Bl/6 mouse that was previously immunized intraperitoneally with MHV (**B**). All mice were sacrificed 8 days later and analyzed for demyelination (marked with a yellow line in **B**). Demyelination was observed only in mice that received adoptively transferred MHV-immune cells (**B**) and not in those that did not (**A**), showing that myelin destruction is largely mediated by T cells during the process of virus clearance. MHV, mouse hepatitis virus.

this process.⁶⁰⁸ CD8 T cells eliminate virus from infected astrocytes and microglia by perforin-dependent pathways, whereas clearance from oligodendrocytes is IFN- γ dependent.^{340,432} However, T-cell-mediated virus clearance is not complete, and antiviral antibody is required to prevent virus recrudescence.³³⁸ Virus persistence in neonatal mice occurs, in part, because virus variants mutated in an immunodominant CD8 T-cell epitope are selected in specific strains of mice, with subsequent evasion of the cytotoxic T-cell immune response.⁴⁵¹ However, this mechanism of immune evasion has not been detected in older mice that are persistently infected with JHMV. The anti-virus CD4 T-cell response, while critical for virus clearance, is also pathogenic. Partial diminution of this response decreases morbidity and mortality, whereas enhancement of the antiviral CD4 T-cell response increases disease severity.¹¹

Other strains of MHV, including MHV-A59, MHV-2, and MHV-3, infect both the liver and the CNS. Most notably, MHV-3 causes a fulminant hepatitis in susceptible strains of mice and chronic neurologic infections in semisusceptible strains.⁶⁴⁹ In susceptible strains, MHV-3 infects macrophages, resulting in up-regulation of several proinflammatory cytokines, including fibrinogen-like protein 2 (FGL2), a transmembrane procoagulant molecule.⁴³¹ FGL2 is also expressed by Foxp3⁺ regulatory T cells.⁵¹¹ Expression of this molecule results in prothrombin cleavage, with consequent disseminated intravascular coagulation (DIC), hepatic hypoperfusion, and necrosis.³⁷⁵ Levels of FGL2 are better predictors of a fatal outcome than virus titers. It is known that the propensity to develop severe disease occurs at a postentry stage because the MHV-3 receptor,

CEACAM1, is expressed in both resistant and susceptible strains of mice. Like JHMV, MHV-3 also infects the CNS; however, infection of this organ occurs only in strains that do not develop a fulminant hepatitis. MHV-3 does not cause a demyelinating disease but rather ependymitis, hydrocephalus, encephalitis, and thrombotic vasculitis.^{315,589} The pathogenesis of these entities is not well studied but appears to be immune mediated. Unlike most other strains of MHV, MHV-3 directly infects T and B cells, resulting in lymphocyte apoptosis and lymphopenia.³⁰³ Lymphopenia, with consequent immunosuppression, facilitates virus persistence and its immunopathologic consequences.

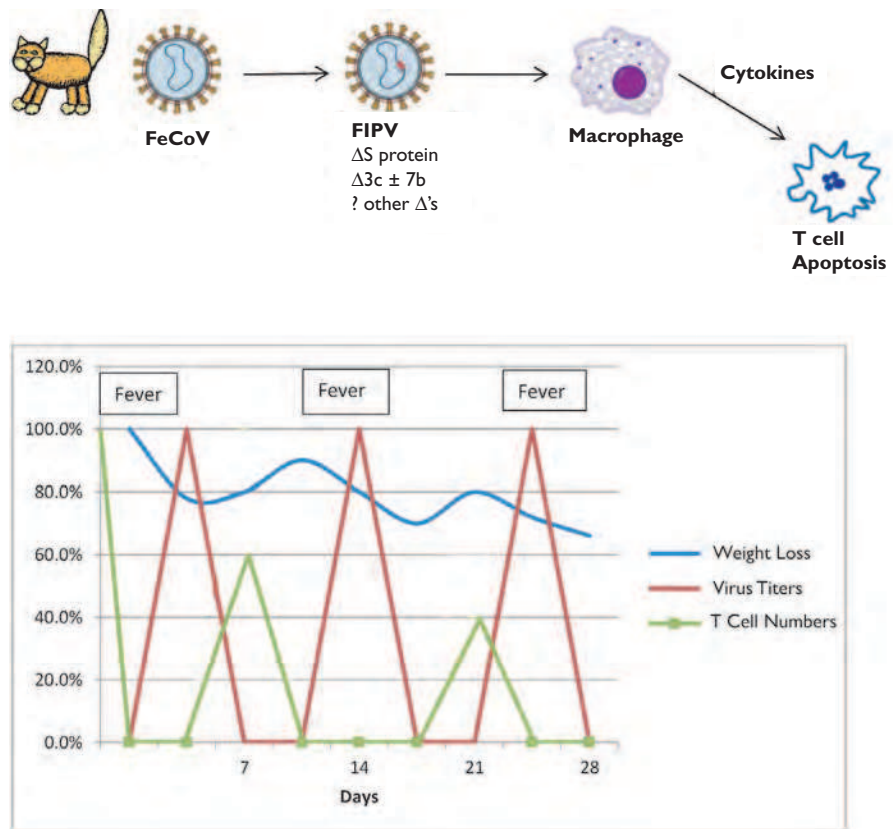

Feline Enteric Coronavirus and Feline Infectious Peritonitis Virus

Feline enteric coronavirus (FeCoV) commonly causes mild or asymptomatic infection in domestic cats and other felines. Two serotypes of FeCoV are recognized, with serotype II strains arising by recombination of serotype I FeCoV with CCoV in dually infected animals.²¹⁶ In some cats infected persistently with FeCoV, mutations in the virus occur, resulting in the development of a lethal disease called *feline infectious peritonitis* (FIP); FIPV is the virulent strain of FeCoV. Virulence correlates with the ability of the virus to replicate in macrophages.¹¹⁰ The nature of the mutations required for transition from FeCoV to FIPV is not well understood, although, at least for serotype II viruses, virulence maps in part to the surface glycoprotein.⁴⁸⁸ This was shown using reverse genetics, in which S proteins from virulent and avirulent strains were swapped and tested for their ability to cause severe disease in cats. FIPV causes a multiphasic

FIGURE 28.12. Recurrent feline infectious peritonitis (FIP). FIP virus—the etiologic agent of FIP—occurs in felines persistently infected with feline coronaviruses.

Upper panels: Mutations in the S glycoprotein and the ORF3b and 7b proteins occur as virus gains the ability to replicate in macrophages. Infected macrophages serve to transport the virus to sites in the host distant from the initial infection. These infected cells also express several cytokines that are believed to contribute to T-cell apoptosis.

Lower panel: Clinical disease is characterized by recurrent bouts of virus replication accompanied by fever and clinical disease. Lymphopenia subsequently occurs as disease progresses. The pattern of disease shown in the figure is representative of progressive disease; however, the rate and extent of recurrence of virus replication, as well as the rate of weight loss and of development of lymphopenia, are variable from animal to animal. (Based on De Groot-Mijnes JD, van Dun JM, van der Most RG, et al. Natural history of a recurrent feline coronavirus infection and the role of cellular immunity in survival and disease. *J Virol* 2005;79:1036–1044.)

disease with relapses that result, ultimately, in immunosuppression, weight loss, and death (Fig. 28.12). Each episode is characterized by increased virus replication, fever, and lymphopenia.¹¹² FIPV does not directly infect lymphocytes. Rather, lymphopenia is believed to be a consequence of infection and activation of macrophages and dendritic cells. Subsequent lymphocyte depletion occurs when cells are exposed to high levels of proinflammatory cytokines, such as tumor necrosis factor, released by these infected cells.²⁰⁵ Virus dissemination occurs when infected macrophages traffic throughout the body and are deposited in the vasculature. Infected macrophages provoke a pyogranulomatous reaction, which is responsible for many disease manifestations of FIP, such as peritonitis and serositis. Another consequence of immune dysregulation is hypergammaglobulinemia. Antibody-antigen complex formation commonly occurs in FIPV-infected cats and may contribute to vascular injury.²⁵² However, its precise role in pathogenesis remains uncertain because it is a late manifestation of disease and may make only a minor contribution to disease progression. Neutralizing antibody against the S glycoprotein enhances FIPV infection of macrophages. Enhanced macrophage infection is mediated by virus entry through Fcγ receptors, although virus binding to fAPN—the specific FIPV host cell receptor—is also likely required.¹¹⁰ This phenomenon has been demonstrated *in vitro* using isolated macrophages and also occurs in cats that have been previously immunized with vectors that express the S glycoprotein.⁵⁸¹ FIPV, but not FeCoV, uptake is augmented by neutralizing antibody that contributes to the propensity of FIPV strains to replicate in macrophages. Although the potential occurrence of antibody-enhanced dis-

ease has hindered vaccine development and was raised as a potential difficulty in development of a live attenuated SARS-CoV vaccine, it has never been demonstrated in the natural infection. In fact, cats infected with FeCoV often develop only low antiviral neutralizing antibody titers.²²⁶

Human Coronavirus Infections

Human Coronaviruses, Other Than Severe Acute Respiratory Syndrome Coronavirus, Associated with Respiratory and Enteric Disease

Prior to 2003, HCoVs were primarily considered to be agents of upper respiratory tract disease and to cause little mortality. In general, whereas coronaviruses were readily isolated from infected birds and other animal species, and serially propagated in continuous cell lines, isolation of HCoVs from infected individuals was only rarely achieved.³⁸⁹ HCoV-229E and HCoV-OC43 were isolated from patients with upper respiratory tract infections in the 1960s.^{210,390,570} There are striking differences in extent of genetic variability when isolates of HCoV-OC43 and HCoV-229E are compared. HCoV-229E isolated at geographically distinct locations show little evidence of variability.⁸⁷ In contrast, isolates of HCoV-OC43 isolated from the United States and from France differ in sequence, and virus from the same geographic area but isolated in different years show considerable sequence variations.⁵⁸⁷ The ability of HCoV-OC43 to tolerate mutations probably accounts for its ability to grow in mouse cells and infect the mouse brain³⁸⁹ as well as its ability to cross species (see the Epidemiology section). In contrast, HCoV-229E does not readily cross species

FIGURE 28.13. Pathologic changes in lungs of patients with SARS. Lung samples obtained on autopsy were examined for pathologic changes following SARS-CoV infection. **A–E:** Hematoxylin and eosin stain showing the progression of SARS pneumonia. Early stages of the SARS infection show edema and early hyaline membrane formation (**A**), hyaline membrane formation (**B**), and increased inflammatory cell infiltration and pneumocyte hyperplasia (**C**). As the disease progresses, fibrotic changes become apparent (**D**). Late manifestations include obliteration of the alveolar volume by fibrous tissue, reactive pneumocytes, and inflammatory cells (**E**). **F:** Viral antigen is detected most prominently during early stages of the infection in macrophages and alveolar pneumocytes. Magnification, $\times 100$. SARS, severe acute respiratory syndrome; SARS-CoV, severe acute respiratory syndrome coronavirus. (Courtesy of Dr. John Nicholls, University of Hong Kong.)

and does not infect mice. Even in mice that are transgenic for expression of the HCoV-229E host cell receptor (human aminopeptidase N [hAPN]), the virus does not grow unless mice are also rendered immunodeficient by genetic disruption of the *STAT1* gene.³⁰⁶

Several new HCoVs were isolated from the respiratory tracts of patients in the post-SARS era. HCoV-NL63, which causes mild respiratory disease, displays homology with HCoV-229E.⁴⁶⁰ Phylogenetic analyses suggest that HCoV-NL63 and HCoV-229E diverged approximately 1,000 years ago.⁴⁶¹ A novel feature of HCoV-NL63 is that unlike HCoV-229E, HCoV-NL63 does not use hAPN as a receptor. Rather, infection of cells is mediated by ACE2, the same molecule that is used by SARS-CoV, an unrelated betacoronavirus.^{219,331} However, unlike SARS-CoV, HCoV-NL63 does not use cathepsin L or require endosomal acidification to infect ACE2-expressing cells²³² and does not cause severe respiratory disease. HCoV-HKU1, isolated from an adult patient in Hong Kong with pneumonia,⁶¹⁵ also generally causes mild respiratory disease.

A role for HCoVs in the etiology of the human disease MS was postulated based on the ability of murine coronaviruses to cause chronic demyelinating diseases. Coronavirus-like particles have occasionally been detected in the CNS of patients with MS and have also been isolated from the brains of patients after passage in mice or murine cell lines. HCoV-229E RNA was detected in about 44% (40 of 90) of human brains tested, with similar frequencies in brains from MS patients and patients who died from other neurologic diseases or normal control subjects.¹³ HCoV-OC43 sequences were

detected in 23% (21 of 90) of brains tested, with 36% incidence in brains from MS patients and 14% in that of controls. Although these results are suggestive, the role of non-SARS-CoV HCoVs in diseases outside the respiratory tract, especially in those involving the CNS, is not proven and requires further investigation.

Severe Acute Respiratory Syndrome Coronavirus Infections

SARS-CoV causes the most severe disease of any HCoV.^{79,310,439,448,602} The virus infects both upper airway and alveolar epithelial cells, resulting in mild to severe lung injury. Virus or viral products are also detected in other organs, such as the kidney, liver, and small intestine, and in stool. Although the lung is recognized as the organ most severely affected by SARS-CoV, the exact mechanism of lung injury is controversial. Levels of infectious virus appear to diminish as clinical disease worsens, consistent with an immunopathologic mechanism.⁴³⁷ However, this conclusion must be tempered because patient samples were obtained from nasopharyngeal aspirates, not from the lungs or other organs. Thus, it is not known whether virus titers in the lung also decrease as virus is cleared. Furthermore, virus titers obtained from patients at autopsy do not provide longitudinal information about the relationship between viral load and disease. The SARS-CoV spike protein may also contribute to disease severity. Administration of the SARS-CoV S protein to mice with pre-existing lung injury enhanced disease severity.^{239,289} ACE2 appears to have a protective role in animals with lung injury, and S protein may exacerbate disease by causing its down-regulation.²⁸⁹

Pathologic findings are nonspecific in patients who died from SARS. Cells in the upper airway were initially infected, resulting in cell sloughing but relatively little epithelial cell damage. However, virus rapidly spread to the alveoli, causing diffuse alveolar damage. This was characterized by pneumocyte desquamation, alveolar edema, inflammatory cell infiltration, and hyaline membrane formation (Fig. 28.13). Over time, alveolar damage progressed, eventually resulting in pathologic signs of acute lung injury (ALI) and, in the most severe cases, acute respiratory distress syndrome (ARDS). Most notably, multinucleated giant cells, originating either from macrophages or respiratory epithelial cells, were detected in autopsy specimens. Although virus could be cultured from infected patients for several weeks, viral antigen was rarely detected in lung autopsy samples after 10 days postinfection.^{137,172,318,417}

Like other coronaviruses, such as MHV and FIPV, SARS-CoV infects macrophages and dendritic cells; however, unlike these two animal coronaviruses, it causes an abortive infection in these cells.^{314,436,533} Several proinflammatory cytokines and chemokines, such as interferon-inducible protein (IP)-10 (CXCL10), monocyte chemoattractant protein (MCP)-1 (CCL2), macrophage inflammatory protein (MIP)-1 α (CCL3), RANTES (regulated on activation normal T cell expressed and secreted) (CCL5), MCP-2 (CCL8), tumor necrosis factor (TNF), and interleukin (IL)-6, are expressed by infected dendritic cells; many of these molecules are also elevated in the serum of SARS-CoV-infected patients.³¹⁰ Lymphopenia and neutrophilia were detected in infected patients and were likely to be primarily cytokine driven.⁶¹³ A potentially confounding factor is that many patients with SARS in the 2003 epidemic were treated with corticosteroids,⁵³⁸ and steroid treatment is a well-known cause of lymphopenia.

An important unresolved issue is how SARS-CoV causes severe respiratory disease in humans. This question is virtually impossible to address in patients, because SARS has not recurred in humans since 2004. SARS-CoV infects several species of animals, including mice, ferrets, hamsters, cats, and monkeys,⁵⁴⁹ although most of these animals develop either mild or no clinical disease, making them not useful for studies of lethal SARS. However, serial passage of SARS-CoV in mice or rats resulted in the isolation of several rodent-adapted strains that cause severe disease in some strains of young mice and rats.^{400,401,478} Most importantly, these strains cause a fatal disease in all aged rodents, paralleling the age-dependent severity observed in infected patients.¹⁴⁰ An age-dependent increase in disease severity is also observed in aged animals experimentally infected with the original human isolates, although disease severity is less than that observed with the mouse-adapted strains.⁴⁷⁹ Animals with severe disease, whether infected with human isolates of SARS-CoV or rodent-adapted strains, show pathologic signs of ALI, increased levels of proinflammatory chemokines and cytokines, and diminished T-cell responses. These observations suggest that immune dysregulation contributes to severe disease in these animals, paralleling pathologic changes observed in infected humans.

Immune Response and Viral Evasion of the Immune Response

As in most viral infections, both the innate and adaptive arms of the immune response are required for successful virus clearance and must be appropriately controlled to minimize

bystander immunopathologic damage. One of the first steps in the host immune response to a coronavirus infection is the production of type I IFN (IFN- α/β). Plasmacytoid dendritic cells (pDCs) are the source for most IFN- α/β produced in coronavirus-infected hosts, although other cells, such as macrophages, also express IFN.^{63,484,657} pDC expression of IFN is mediated by signaling through a toll-like receptor (TLR) 7- and interferon regulatory factor (IRF) 7-dependent pathway. The importance of IFN signaling in the initial immune response to coronaviruses was shown using mice that are defective in expression of the IFN- α/β receptor (IFNAR^{-/-}).^{63,244} Infection of IFNAR^{-/-} mice with mildly virulent strains of MHV results in rapid and uniformly fatal diseases. Additionally, the importance of the IFN response is also evidenced by the multiple IFN evasive mechanisms that coronaviruses employ, as described later. Although the importance of the IFN response is well established, little is known about which specific IFN-induced proteins are most critical for protection. Ribonuclease L (RNase L) appears to have a role in the immune response to neurotropic strains of MHV²⁴³; however, whether this molecule is also important in the immune response to nonneurotropic strains of coronavirus remains to be determined.

Once the initial IFN response is induced, virus clearance requires expression of proinflammatory cytokines and chemokines and their receptors, such as CCL2, CXCL9, CXCL10, CCL3, to mediate T-cell and macrophage trafficking to sites of infection.³¹ Infection of the CNS also requires breakdown of the blood-brain barrier, which is partially neutrophil dependent. In the absence of neutrophils or of neutrophil chemoattractants, such as CXCL1 and CXCL2, breakdown does not occur, resulting in more severe disease.⁶⁵⁸ A robust T-cell response is required for destruction of infected cells and clearance of infectious virus. T-cell responses are poor in felines with progressive FIP (see Fig. 28.12) and in some strains of mice with severe SARS-CoV infections.^{112,653} Virus is not cleared in MHV- or SARS-CoV-infected mice that lack T cells, again demonstrating the importance of the response in clearance.⁶²¹ Both CD4 and CD8 T-cell epitopes have been identified in mice infected with MHV or SARS-CoV and in patients with SARS. Most epitopes are located on the N, M, and S proteins.^{78,345,444,447} Once virus has been cleared, the proinflammatory response must be controlled to prevent immunopathology. In MHV-infected mice, regulatory CD4 T cells, characterized by Foxp3 expression, are important for dampening a potentially pathogenic immune response.⁵⁶⁵ IL-10, another anti-inflammatory factor important for minimizing immunopathologic changes in MHV-infected mice, is expressed predominantly by virus-specific CD4 and CD8 T cells in the infected brain.^{339,566} As described earlier for MHV-infected mice, T cells are responsible for initial virus clearance; however, an effective antiviral antibody response is required to prevent virus recrudescence.³³⁸ Similarly, a robust neutralizing antibody response was detected in survivors during the 2002–2003 SARS outbreak.⁵⁶

Coronaviruses use several approaches, both active and passive, to evade the host IFN response and thereby establish a productive infection (Table 28.4). Coronaviruses replicate in DMVs (see Fig. 28.8), which may shield viral RNA from recognition by intracellular sensor molecules, such as RIG-I, MDA5, and TLR3. Thus, in fibroblasts or conventional DCs infected with MHV or SARS-CoV, no IFN is induced.^{173,586,656} However,

M protein	SARS-CoV	Inhibits IRF3 activation	518

nsp, nonstructural protein; MHV, mouse hepatitis virus; SARS-CoV, severe acute respiratory syndrome coronavirus; SARSr, severe acute respiratory syndrome-related; BatCoV, bat coronavirus; TGEV, transmissible gastroenteritis virus; mRNA, messenger RNA; IFN, interferon; PL^{pro}, papain-like protease; HCoV, human coronavirus; IRF, interferon regulatory factor; NF- κ B, nuclear factor-kappaB; ADRP, adenosine diphosphate-ribose-1"-phosphatase; MDA5, melanoma differentiation-associated gene 5; IFIT, IFN-induced proteins with tetratricopeptide repeats; ORF, open reading frame; STAT, signal transducers and activators of transcription; PKR, double stranded RNA-dependent protein kinase; OAS/RNase L, oligoadenylate synthetase/ribonuclease L.

the IFN response does not appear to be actively blocked in these cells, because infection with Sendai virus or exposure to poly I-C induces IFN. In some cells, such as macrophages, microglia, and oligodendrocytes, coronaviruses induce an IFN response by signaling through MDA5, and in oligodendrocytes, RIG-I.^{328,484} To counter IFN induction through activation of MDA5, all coronaviruses express a 2'-O-methyltransferase (nsp16; see the Expression of the Replicase-Transcriptase Complex section). In the absence of 2'-O-methylation, viral RNA induces a potent MDA5-dependent IFN response, which limits replication in wild-type animals but not in those deficient in IFNAR expression⁶⁶⁵ (see Table 28.4). Additionally, SARS-CoV, but not MHV nsp3, inhibits IFN induction by antagonizing IRF3 and NF- κ B function.^{136,174}

Once IFNs are expressed, they bind to IFNAR, resulting in the up-regulation of a large number of interferon-stimulated genes (ISGs). Several coronaviral proteins inhibit either IFN signaling or specific ISGs (see Table 28.4). In addition to inhibiting IFN induction, the nsp16 2'-O-methyltransferase counters the ability of IFN-induced proteins IFIT1 and IFIT2 (also referred to as ISG56 and ISG54) to inhibit translation of viral mRNA.¹⁰⁶ N protein inhibits IFN signaling, as do SARS-CoV, MHV and TGEV nsp1, and SARS-CoV ORF3b and ORF6 proteins.¹⁷³ The mechanism of action of some of these proteins has been elucidated. The N protein interferes with 2',5'-oligoadenylate synthase-associated RNase L activity.⁶³⁷ Nsp1 appears to enhance host cell mRNA degradation and inhibit host cell protein synthesis, with specific effects on IFN signaling.^{259,598,666} The karyopherin complex is required for nuclear import of STAT1, a critical component of the IFN signaling pathway, as well as the import of many other host proteins. SARS-CoV ORF6, by binding karyopherin α 2, sequesters karyopherin β 1 in the cytoplasm, indirectly inhibiting nuclear translocation of STAT1.¹⁷⁵

EPIDEMIOLOGY

Human Coronaviruses Other Than Severe Acute Respiratory Syndrome Coronavirus

Four known coronaviruses—HCoV-OC43, HCoV-229E, HCoV-NL63, and HCoV-HKU1—are endemic in human populations. HCoV-OC43 and HCoV-229E cause up to 30% of all upper respiratory tract infections, based on several prospective studies.^{245,389} The variable range of detection reflects year-to-year variability, detection methods, season, and age of subjects. These studies also suggest that peak activity occurs every 2 to 4 years.^{184,264,397} In temperate climates, infections occur predominantly in the winter and early spring. HCoV-OC43 and HCoV-229E have also been associated with severe pneumonia in neonates and aged populations, especially those with underlying illnesses, such as chronic obstructive pulmonary disease, or those requiring intensive care.^{163,198} The high rate of HCoV infections early in life and the pattern of infections during outbreaks demonstrate that HCoVs are efficiently transmitted in human populations, most likely via large and, to a lesser extent, small droplets. Serologic studies suggest that infection with HCoV-229E and HCoV-OC43 frequently occurs in young children and then repeatedly throughout life.^{245,264,556,557} Neutralizing antibodies against HCoV-OC43 or HCoV-229E have been detected in about 50% of school-age children and up to 80% of adults.^{264,389,458}

HCoV-NL63 and HCoV-HKU1 also have worldwide distributions, causing up to 10% of respiratory tract infections.^{1,460} Initial reports suggested that HCoV-NL63 was associated with severe respiratory disease; however, subsequent population-based studies showed that most patients developed mild disease, similar to those infected with HCoV-229E or HCoV-OC43. HCoV-NL63 is also an important etiologic agent of acute laryngotracheitis (croup).¹ HCoV-HKU1 was initially identified in an elderly patient with severe pneumonia,

FIGURE 28.14. SARS-CoV spread from infected bats to infect humans in wet markets in Guangdong Province, China.

SARS-related coronaviruses were detected in Chinese horseshoe bats and other bat species in China. The virus spread to human populations, likely animal handlers, in wet markets in Guangdong Province. Spread occurred either indirectly, via infection of exotic animals such as Himalayan palm civets, or directly, with subsequent human transmission to Himalayan palm civets and other exotic animals. This transmission occurred more than once, because a fraction of the animal handlers were positive for anti-SARS-CoV antibody.²⁰³ In one episode, a physician taking care of an animal handler became infected. He then flew to Hong Kong and stayed at Hotel M, where he inadvertently infected several other people staying at the hotel, probably via superspreading events. These infected individuals then flew to other countries, resulting in the international outbreak. SARS-CoV, severe acute respiratory syndrome coronavirus; SARS, severe acute respiratory syndrome.

although more recent studies suggest that it is associated with both mild and severe respiratory infections.^{460,615}

Severe Acute Respiratory Syndrome

During the 2002–2003 epidemic, SARS-CoV was isolated from several exotic animals, including Himalayan palm civets (*Paguma larvata*) and raccoon dogs (*Nyctereutes procyonoides*), in wet markets in Guangdong Province in China²⁰³ (Fig. 28.14). Subsequent investigations showed that SARS-CoV could not be detected in these animals in the wild but that severe acute respiratory syndrome–related coronaviruses

(SARSr-CoV) could be isolated from wild bats in China^{308,332} (see Table 28.1). Bats are now considered to be the ultimate source for SARS-CoV, with probable infection of human populations occurring after initial adaptation to animals in Chinese wet markets. Sequences from several distinct SARSr-CoVs have been amplified from Chinese horseshoe bats from Hong Kong and several provinces in China, and 30% to 85% of bats of this genus (*Rhinolophus*) had serologic evidence of infection with a SARSr-CoV. *N* gene sequences for three SARSr bat coronaviruses (BatCoVs) differed by 3% to 6%, similar to the level of difference between the *N* proteins

FIGURE 28.15. Role of superspreading events in SARS-CoV epidemics. SARS-CoV spread in Singapore in 2003, illustrated here, via superspreading and non-superspreading events. Most infected persons transmitted virus to fewer than five susceptible contacts. However, in a few instances, infected individuals were highly contagious, resulting in infection of larger numbers of contacts. The basis for superspreading events is not known but likely is a manifestation of larger virus burdens in a few infected patients. **A:** Probable cases of SARS by reported source of infection. **B:** Number of probable cases of SARS, by date of onset of fever and probable source of infection. SARS-CoV, severe acute respiratory syndrome coronavirus; SARS, severe acute respiratory syndrome. (From Leo YS, Chen M, Heng BH, et al. Severe Acute Respiratory Syndrome — Singapore, 2003. *Morb Mortal Wkly Rep* 2003;52:405–411.)

of each of these viruses and that of SARS-CoV. This degree of difference between SARS-CoV and the various SARSr-BatCoVs indicates that the precise source of the 2002–2003 SARS outbreak viruses remains unknown. Neither SARS-CoV nor reconstructed BatCoVs can use the Chinese horseshoe bat ACE2 protein to enter target cells, raising the possibility that the bat host receptor is unrelated to ACE2²⁶; alternatively, the virus that was the actual progenitor for SARS-CoV may have originated from a BatCoV distantly related to the SARSr-CoVs identified thus far.²²⁵

Serologic studies demonstrated that SARS-CoV had not circulated to a significant extent in humans prior to the outbreak in 2002–2003.^{64,320} However, some persons working in wild animal wet markets in China had serologic evidence of a SARS-CoV-like infection acquired before the 2003 outbreak but reported no SARS-like respiratory illness.²⁰³ Thus, virus may have circulated in these wild animal markets for a few years, with the SARS outbreak occurring only when a confluence of factors facilitated spread into larger populations. Although animals were the original source of SARS, its global spread occurred by human-to-human transmission. Transmission appeared to occur through close contact—that is, direct person-to-person contact, fomites, or infectious droplets and probably aerosols in some instances.⁴³⁸ Because transmission usually only occurred after onset of illness and most efficiently after the patient was sufficiently ill to be hospitalized, most spread occurred in household and healthcare settings but infrequently in other settings.⁴⁴⁰ There was also substantial patient-to-patient variation in efficiency of transmission, which, in part, was associated with the degree of illness severity. Many susceptible persons were infected in superspreading events; however, fortunately, only a minority of infected individuals were involved in this type of spread^{342,475} (Fig. 28.15). Superspreading events, which occurred when a single individual infected multiple susceptible contacts, may have resulted from high virus burdens or a tendency for these individuals to aerosolize virus more efficiently than most infected

persons. Most infected individuals spread the virus to only one or a few susceptible persons, suggesting that virus spread was relatively inefficient.^{342,475} The outbreak was partly controlled using quarantining, and the lack of efficient spread contributed to the success of this approach. Because the SARS outbreak was controlled in June 2003, only 17 cases of SARS were subsequently confirmed, and none of these occurred after June 2004. Thirteen of these 17 cases resulted from laboratory exposures, including 7 secondary cases associated with one of the cases.³³⁶ The other 4 cases occurred in southern China and resulted from exposure in the community, presumably to SARS-CoV–infected animals from wild animal markets.³³⁴

Genetic Diversity of Coronaviruses

The SARS outbreak demonstrated the ability of coronaviruses to cross species, as the virus, naturally a bat virus, was able to infect small mammals, such as the Himalayan palm civet, and humans. Initially predicted from studies of coronavirus-infected cultured cells,²³ the ability of coronaviruses to cross species was also demonstrated when the betacoronaviruses HCoV-OC43, PHEV, and BCoV were analyzed¹⁵⁸⁸ (Fig. 28.16). It is estimated that PHEV diverged from HCoV-OC43 and BCoV 100 to 200 years ago, whereas HCoV-OC43 and BCoV diverged about 100 years ago. Whether the common ancestor of HCoV-OC43 and BCoV was a human or bovine virus is not known. More recently, BCoV has crossed species to infect many ruminants, including elk, giraffe, and antelope,⁴ and also canines.^{159,160} Other phylogenetic studies suggest that the porcine alphacoronavirus TGEV resulted from cross-species transmission of a CCoV.³⁵⁵

In addition to their ability to cross species, coronaviruses readily undergo recombination (see the Viral RNA Synthesis section). Recombination events between canine (CCoV-I) and feline (FeCoV-I) coronaviruses and an unknown coronavirus resulted in the appearance of two novel viruses (CCoV-II and FeCoV-II).³⁵⁵ In another illustration, new strains of IBV

FIGURE 28.16. Coronaviruses mutate and recombine to cross species barriers. Phylogenetic analyses indicate that HCoV-OC43, BCoV, and PHEV shared a common ancestor and diverged about 200 years ago. More recently (100–130 years ago), HCoV-OC43 and BCoV diverged; however, it is not known whether BCoV infected human populations or HCoV-OC43 crossed species barriers to infect bovids. BCoV then spread to many ruminants and to dogs, probably via contact with infected domesticated cows. HCoV, human coronavirus; BCoV, bovine coronavirus; PHEV, porcine hemagglutinating encephalomyelitis virus.

have been detected in chicken populations and appear to have resulted from recombination between circulating vaccine and wild-type IBV strains.²⁸⁴ This propensity for recombination has raised concerns about the use of live attenuated coronavirus vaccines (see the Prevention section).

CLINICAL FEATURES

Human Coronaviruses Other Than Severe Acute Respiratory Syndrome Coronavirus

In humans, coronaviruses have been clearly shown to cause respiratory disease, including its most severe manifestation—SARS. HCoVs have occasionally been implicated in enteric disease, particularly in newborns, using electron microscopy.^{185,270,365} Electron microscopy has been used in these studies, because efforts to propagate human enteric coronaviruses in tissue culture cells have thus far been unsuccessful, hindering further studies. Because other particles in stool specimens (e.g., cellular membranes) can have similar morphology to coronaviruses, electron microscopic detection of coronavirus particles in stools is not considered diagnostic of infection. However, polymerase chain reaction (PCR) assays designed to detect coronavirus RNA sequences in pathologic specimens will now make it possible to determine whether these viruses play a role in enteric diseases. It seems likely that coronaviruses will be the etiologic agent in a fraction of patients with gastroenteritis, given the ability of these viruses to cause enteritis in a variety of domestic and companion animals.

Clinical features of infections in humans follow two distinct patterns: one for the non-SARS-CoV coronaviruses (i.e., HCoV-229E, -NL63, -OC43, -HKU1), and one for the zoonotic coronavirus SARS-CoV. Among the HCoVs, HCoV-229E and HCoV-OC43 were extensively characterized in volunteer studies in the 1960s.³⁸⁹ Human volunteers inoculated intranasally with respiratory coronaviruses developed symptoms that included fever, headache, malaise, chills, rhinorrhea, sore throat, and cough, with peak infection observed 3 to 4 days following infection. About half of the volunteers challenged with virus developed illness, and approximately 30% were asymptotically infected, as indicated by detection of virus in the upper respiratory tract. Symptoms lasted for a mean of 7 days, with a range of 3 to 18 days. Natural infection in both adults and children is also usually associated with a common

cold-like illness.^{44,389} Natural infection is probably acquired in a fashion similar to that for many other respiratory viruses (i.e., inoculation of infectious secretions from infected persons or fomites onto mucous membranes of the upper respiratory tract or inhalation of infectious droplets), with primary infection of ciliated epithelial cells in the nasopharynx.³ Destruction of these cells, combined with exuberant production of chemokines and cytokines by resident and infiltrating cells, results in signs and symptoms of clinical illness.

HCoV infections are also occasionally associated with lower respiratory tract disease in children and adults. Coronaviruses have been detected in children hospitalized with lower respiratory tract disease at varying rates, although usually less than 8% of patients.^{88,155,179,556,557,572} One caveat is that coronaviruses are also sometimes detected in well, control patients; thus, the presence of virus may not be etiologically related to the illness.¹⁰⁸ Coronavirus infection has also been detected in adults with acute respiratory tract illness, including about 5% of those hospitalized with lower respiratory tract disease.^{108,155,163,182,198} Studies using PCR to detect viral RNA in middle ear fluids suggest that coronaviruses, like other respiratory viruses, can cause otitis media.^{454,455} In addition, HCoVs have been associated with wheezing and exacerbations of asthma.^{245,556} HCoV-NL63 and HCoV-HKU1 have also been detected in persons with acute upper and lower respiratory tract illness,^{1,108,182,556,557} and as described earlier, HCoV-NL63 is associated with croup in children younger than 3 years.⁵⁷⁴ Studies of natural infection and volunteer studies have shown that reinfection with coronaviruses is common, demonstrating that infection does not induce stable protective immunity.^{245,264,389} For example, previously infected volunteers developed symptomatic disease if infected 1 year later with the same strain of HCoV-229E.⁴⁷⁰

Severe Acute Respiratory Syndrome Coronavirus Infections

In contrast to the mild illness usually associated with HCoV infections, SARS-CoV have nearly always resulted in a serious lower respiratory tract illness that required hospitalization, often in an intensive care unit (up to 20% of infections)⁴³⁸ (Fig. 28.17). In the 2002–2003 epidemic, approximately 8,000 individuals were infected, with an overall mortality rate of 10%. Disease severity increased proportionally with age. Thus, no mortality occurred in patients younger than

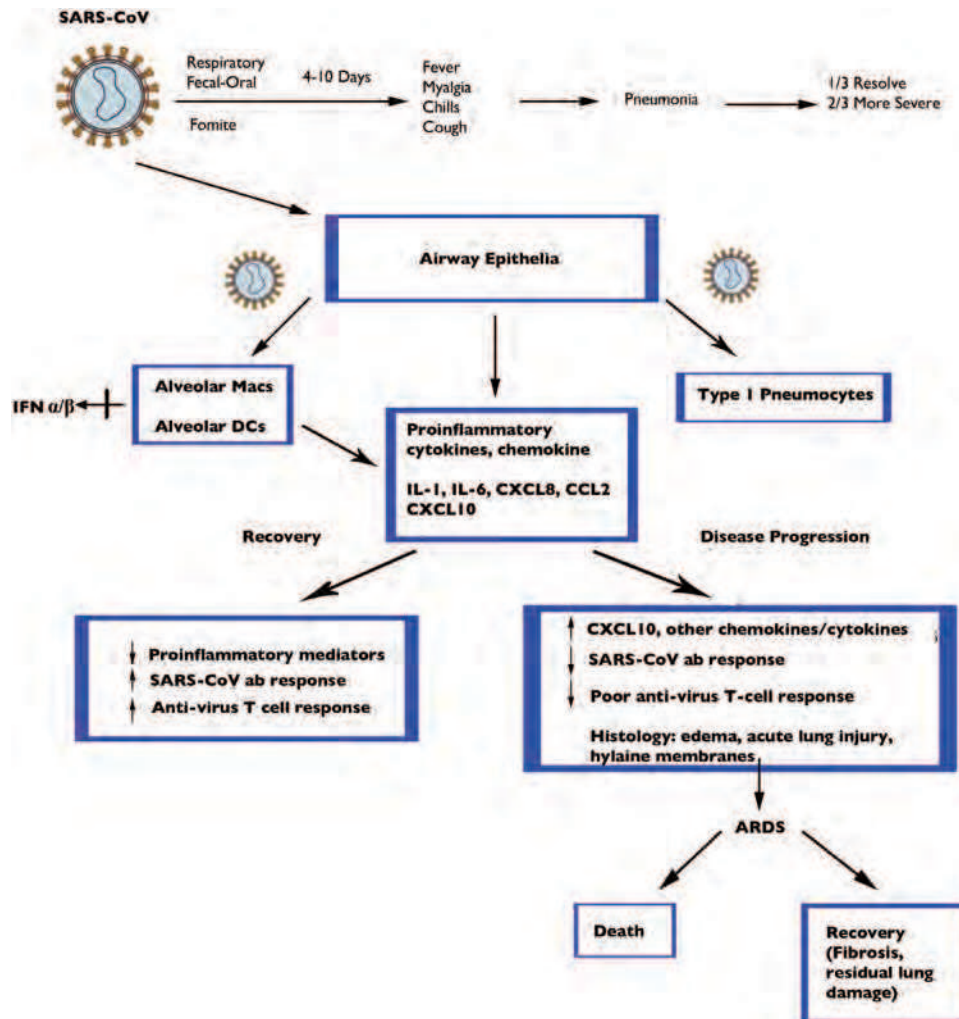

FIGURE 28.17. Clinical disease in patients infected with SARS-CoV. SARS-CoV spread to susceptible individuals via respiratory and fecal–oral routes and, less commonly, if at all, via fomites. Virus replication was initiated in the upper airway epithelial cells, based primarily on animal studies and *in vitro* studies using primary cultures of airway epithelial cells. Virus subsequently spread to the lower respiratory tract, with infection of type 1 pneumocytes and macrophages and dendritic cells most prominent. The infection of the latter two cell types was abortive, resulting in production of proinflammatory cytokines and chemokines such as CXCL10 and CXCL8 but not type 1 IFN. In patients who recovered, expression of proinflammatory cytokines diminished, and robust antiviral antibody responses were detected. In patients who developed progressively more severe disease, cytokine production continued and patients remained lymphopenic without developing an effective anti-SARS-CoV antibody response. Some of these patients died, and significant long-term morbidity was found in many of the survivors. SARS-CoV, severe acute respiratory syndrome coronavirus; IFN, interferon.

24 years, although about 50% of infected individuals older than 60 years succumbed to the infection. Mortality was also greater in patients with underlying disease. Clinical disease in patients with SARS was not diagnostic; however, some features were more common in SARS patients compared to those infected with other pathogens.^{35,318,437,438} Illness usually had an onset of 4 to 7 days, although occasionally an incubation period of as little as 2 days or as long as 10 to 14 days was observed. Disease was characterized by systemic symptoms such as fever, malaise, and myalgias. Unlike many other respiratory tract infections, upper respiratory tract signs and symptoms such as rhinorrhea, sore throat, and nasal congestion were not common, although they

still occurred in a minority of patients. The first lower respiratory tract symptoms (usually a nonproductive cough and shortness of breath) developed several days after onset of systemic symptoms. Respiratory symptoms were often accompanied by evidence of involvement of other organ systems. Thus, whereas diarrhea occurred at disease onset in fewer than 25% of patients, up to 70% developed gastrointestinal disease during the course of the illness. Most patients developed abnormal liver function tests (70%–90%) and lymphopenia (70%–95%), with a substantial drop in both CD4 and CD8 T-cell numbers.^{104,438} Patients who failed to resolve their illness often had progressive respiratory failure leading to ARDS and death weeks to months

after illness onset.^{56,171,321} In these patients, lymphocyte and platelet counts remained abnormally low, whereas neutrophilia and elevated titers of virus or viral RNA in clinical specimens for prolonged periods of time were common features. Asymptomatic or mild illness was uncommon, as illustrated by studies of exposed healthcare workers. In these studies, fewer than 1% of those without a SARS-like illness had serologic evidence of infection.^{70,218,466} Most survivors of SARS-CoV infection achieved full recovery, although pulmonary function abnormalities sometimes took months to subside.^{86,626} Some, however, had persistently abnormal pulmonary function. Curiously, a fraction of survivors showed more evidence of neurologic or psychiatric disease than expected based on the degree of respiratory illness or steroid use. Although brains were not commonly studied during the 2002–2003 epidemic, a few studies did demonstrate SARS-CoV infection of the brain, suggesting that CNS infection may have occurred in some cases.^{84,201,307,316}

DIAGNOSIS

Most HCoV infections, other than SARS-CoV, are not diagnosed because they cause mild, self-limited upper respiratory disease, and no specific therapy is available. Diagnosis is laboratory-based because coronavirus infections cannot be distinguished clinically from other causes of upper respiratory tract infections, such as rhinoviruses. However, in some clinical settings, such as in hospitalized patients with pneumonia and in epidemiologic studies, specific diagnosis is important. Coronavirus infections in animals and humans were initially diagnosed by isolation of infectious virus, by electron microscopy, and in serologic assays, with the caveat that some coronaviruses, especially those in the stool, are not easily cultured. HCoV-229E and related alphacoronaviruses have sometimes been isolated in human diploid cell lines. Other HCoVs, most notably HCoV-OC43, initially required cell organ culture systems for isolation,³⁸⁹ although this virus can now be grown in tissue culture cells. HCoV-NL63 can infect monkey kidney LLC-MK2 cells or Vero cells,^{170,460,573} whereas HCoV-HKU1 has been grown only in primary human airway epithelial cells.⁴⁶³ RT-PCR-based methods and immunofluorescence assays (IFA) for virus antigen have largely replaced these other methods for the diagnosis of respiratory coronavirus infections.^{108,156,163,198,392} PCR primers can be designed to be broadly reactive or strain specific, based on primer location and design. With a sensitive system to detect the PCR amplicon (e.g., a real-time assay), fewer than five RNA copies in the reaction mixture can be consistently detected.¹⁵⁶ A multiplex real-time RT-PCR assay has also been described that is able to detect all four respiratory coronaviruses and may become the diagnostic method of choice.¹⁸⁴

Electron microscopic examination of clinical material, although laborious, contributed to the identification and characterization of many coronaviruses, including SARS-CoV.^{143,288,389,439} At present, electron microscopy is used most commonly to identify coronaviruses in patients with enteritis,²⁷⁰ because none of these coronaviruses have been cultured; however, because other particles in clinical specimens can resemble coronaviruses and coronaviruses may be present without causing disease, identification of such particles does not confirm infection.

Various serologic assays have been used to detect coronavirus infections, including complement fixation, hemagglutination inhibition (HI) for viruses with an HE protein (i.e., some betacoronaviruses), neutralization, IFAs, and enzyme-linked immunoassays (EIAs). Initially, these assays used virus lysates or inactivated whole virus; more recently, cloned expressed proteins, synthesized peptides, and pseudoviruses have been used as antigens for serologic assays.^{319,357,389,418,458,558}

SARS or another coronavirus infection of equivalent severity presents a different diagnostic situation. A specific diagnosis is critical because a positive result will guide clinical management and have public health implications. However, testing should only be considered when, based on the likelihood of an exposure and clinical features of the illness, infection is plausible. SARS-CoV was initially isolated in fetal rhesus kidney cells and Vero cells; however, during the 2002–2003 epidemic, a combination of serologic and RT-PCR assays, not virus culture, were used to detect and confirm SARS-CoV infection.⁴⁴⁰ With very sensitive PCR assays (e.g., a nested or real-time PCR assay) and RNA extraction procedures that increased the amount of specimen available for the assay, the positivity rate in respiratory specimens obtained during the second and third days of illness increased from less than 40% to more than 80% as the epidemic progressed.⁴⁵⁹ SARS N protein EIA was positive in 50% to 80% of serum specimens collected during the first week of illness⁷⁴ and in more than 50% of respiratory and stool specimens collected during the second and third weeks of illness.³⁰⁹ SARS-CoV-specific antibodies were usually detected by 14 days into the illness, although sometimes not until 4 weeks after infection.^{229,233} Whereas RT-PCR provided the best way to make an early diagnosis, serologic assays were important in confirming or ruling out SARS-CoV as the cause of infection. Because serum specimens from persons not infected with SARS during the 2002–2003 outbreak have rarely tested positive for SARS-CoV antibodies,³²⁰ a single serum specimen positive for SARS-CoV antibodies was usually considered diagnostic; a negative test on a serum specimen collected late in the illness (28 days or later after onset of illness) could be used to rule out SARS-CoV infection.

TREATMENT

At present, there are no antiviral drugs for HCoV infections, and therapy is supportive. During the major part of the SARS epidemic, most patients were treated with ribavirin or high-dose steroids, based on the idea that the virus would be susceptible to ribavirin and steroids might diminish immune-mediated bystander damage.⁵³⁸ Late in the outbreak, based on their ability to inhibit SARS-CoV replication *in vitro* and/or in experimental animals, IFN- α , SARS convalescent-phase immune globulin, and lopinavir plus ritonavir (two protease inhibitors licensed for the treatment of HIV) were used to treat patients.^{65,85,89,356,530} However, a large-scale review of all of these therapies concluded that whereas some showed efficacy in inhibiting SARS-CoV replication in tissue culture cells, none showed a beneficial effect in patients.⁵³⁸ The molecular biology of coronavirus infection suggests several potential targets for antiviral drugs, including the viral RdRp, virus-encoded proteases, host cell receptors used by the virus for entry, and the viral S glycoprotein. Subsequent to the outbreak, several antiviral drugs targeting these

viral proteins or processes have been developed and evaluated for their ability to inhibit SARS-CoV replication *in vitro*. These include specific coronavirus protease inhibitors,⁴⁶⁸ monoclonal antibodies that inhibit SARS-CoV binding to cells,⁵⁵¹ peptides from the heptad repeat regions of the S protein or from ACE2 that inhibit receptor binding or fusion,^{40,211} and small interfering RNAs.⁷¹ If SARS or another severe coronavirus-mediated disease emerges, *in vitro* and animal model studies of antiviral drugs will be used to guide treatment.

PREVENTION

No vaccines are available to prevent HCoV infection; however, vaccines against common veterinary coronaviruses, such as IBV and CCoV, are routinely used to prevent serious disease in young animals. Efforts are ongoing to improve these vaccines and to enhance safety and efficacy while minimizing the likelihood of reversion to a virulent strain.⁴⁹² In addition, various SARS-CoV vaccines have been developed, including inactivated whole virus, live virus vectors expressing single viral proteins and recombinant proteins, and DNA vaccines.^{10,480} Nearly all of these vaccines express the surface glycoprotein and are designed to induce SARS-CoV neutralizing antibodies. For some of these vaccines, efficacy has been demonstrated in animal models. Large stocks of anti-SARS-CoV neutralizing antibody have been prepared and will be used for passive immunization of healthcare workers and other high-risk personnel if SARS recurs.

In general, live attenuated vaccines are likely to be most effective in inducing protective immune responses against coronaviruses. This has been illustrated elegantly in the case of TGEV—an important cause of neonatal diarrhea and death in swine. In the mid-1980s, a naturally occurring, attenuated variant of TGEV—PRCoV—was identified in pig populations. This virus, which causes mild disease and no enteritis, induces an immune response in pigs that is protective against TGEV and largely eliminated it from dually infected populations.³¹² Live attenuated vaccines induce not only neutralizing antibodies but also antiviral T-cell responses, which are required for virus clearance from infected cells in SARS and other coronavirus infections. However, the development of live coronavirus vaccines is challenging.⁴⁹² First, in many instances, natural infection does not prevent either subsequent infection or disease, therefore an effective vaccine would need to be superior to immunity induced naturally. Second, the genetic and antigenic variability of coronaviruses and their ability to readily recombine hinder vaccine development. Thus, a vaccine may not provide equal protection from all antigenic variants, and subsequent recombination with vaccine strains could increase the number of different strains circulating in the wild. As an example, recombinants of IBV vaccine strains with virulent wild-type strains have caused disease outbreaks in chicken flocks.^{249,596} In addition, the finding that immunization with an S protein-expressing FIPV vaccine led to more severe disease after subsequent natural infection raises the concern that other coronavirus vaccines might also enhance, rather than protect, from disease.⁵⁸¹ Several strategies to minimize the likelihood of recombination and to attenuate candidate vaccines without compromising efficacy have been recently described. These include engineering viruses with deletions in *nspl*, important for the anti-IFN response,⁶⁶⁶ or in E

protein, important for virus assembly.¹²⁴ In other approaches to minimizing the likelihood of recombination of vaccine viruses, the coronavirus genome has been reconstructed, changing the order of structural genes at the 3' end¹²¹ or modifying the leader and body TRSs (see the Viral RNA Synthesis section) to eliminate homology with natural virus sequences.⁶⁴⁴

In the absence of effective vaccines and antiviral drugs, the most important ways to prevent coronavirus infections are a highly active public health surveillance system and good infection control practices. This was demonstrated unequivocally during the SARS outbreak in 2002–2003, in which sharing of information by national public health agencies and governments and involvement of international agencies such as the World Health Organization resulted in the rapid identification of a coronavirus as the cause of SARS and implementation of measures that minimized spread. At the local level, strict attention to good isolation and infection control practices and identification and management of exposed persons (contacts) minimized human-to-human spread of the virus within a few months of its global spread. The low risk of SARS-CoV transmission before hospitalization and the low rate of asymptomatic infection facilitated the efficacy of these public health measures.^{70,218,466} The identification of cases of laboratory-acquired SARS-CoV, with subsequent transmission to others after one of these cases,^{334,336} reinforces the importance of strict attention to safe laboratory practices. These practices include handling the virus in the appropriate type of facility, using standardized operating procedures, and providing appropriate training and medical surveillance programs for staff.

PERSPECTIVES

Many important problems remain to be resolved by future studies of coronaviruses. One critical task will be to broaden our picture of how coronaviruses jump between species. We need to know whether cross-species viral trafficking events, both abortive and successful, are rare or common. Although there has been a recent expansion of our knowledge of spike protein interactions with receptors and associated proteases, we cannot yet fully gauge the height of the barrier preventing productive adaptation by a spike protein to new receptors and proteases. Such information will be directly relevant to forestalling or coping with the re-emergence of a SARS-related (or other) coronavirus from ubiquitous bat reservoirs. Related to this is the challenge of developing *in vitro* culture systems for virus species that are currently only known through their genomic sequences. A second area of crucial importance will be to further develop our understanding of the immunopathogenesis of the more severe human and animal coronaviruses and to more precisely delineate the correlates of immune protection. This will better inform the effective design and evaluation of vaccines for control of these agents. Finally, one of the most exciting areas of future research will be to address the many gaps in our basic knowledge of the intricacies of the coronavirus RTC—the largest and most complicated machinery of RNA synthesis found in any RNA virus. The past few years have seen tremendous advances in this field, particularly in structural and biochemical studies, and it is likely that progress will continue apace. A long-term goal will be the total *in vitro* reconstitution of coronavirus RNA synthesis, which would definitively demonstrate the roles

of the many viral replicase subunits as well as those of putative host factors. It can be expected that studies of this type will reveal fundamental principles common to all RNA-dependent RNA synthesis, in addition to mechanisms unique to the order *Nidovirales*. Knowledge derived from this enterprise will be critical for the design of antiviral drugs to combat diseases caused by existing and emerging coronaviruses.

HISTORY AND CLASSIFICATION OF ARTERIVIRUSES

The family *Arteriviridae*⁶⁸ was established in 1996 and currently comprises the following four enveloped, plus-stranded RNA viruses: equine arteritis virus (EAV), lactate dehydrogenase-elevating virus (LDV) of mice, porcine reproductive and respiratory syndrome virus (PRRSV), and simian hemorrhagic fever virus (SHFV). Three of these (EAV, LDV, and SHFV) were first isolated and characterized about 50 years ago.^{62,161,189} The porcine arterivirus PRRSV emerged only about 20 years ago,^{36,227} causing vast epidemics of a previously unknown reproductive and respiratory disease in swine in both Europe (genotype I) and North America (genotype II). Remarkably, the subsequent molecular characterization of PRRSV strains from both continents revealed considerable genetic differences, suggesting that the two PRRSV genotypes evolved separately and are only distantly related to a common ancestor.^{152,170} PRRSV infection can cause high-mortality disease outbreaks and has developed into the most prevalent disease of swine worldwide. Recently, a large outbreak of highly virulent PRRSV affected the Asian pig industry, causing enormous economic losses.^{194,246}

In general, the consequences of arterivirus infection can range from an asymptomatic, persistent or acute infection to abortion or lethal hemorrhagic fever.^{199,226} EAV is capable of inducing a variety of symptoms, including necrosis of the small muscular arteries from which the name of the family prototype EAV was derived. The name of the mouse arterivirus LDV is derived from the increase in the level of lactate dehydrogenase (LDH) caused by LDV infection.¹⁶¹ The virus, which has been used extensively as an *in vivo* research model, is able to escape immune surveillance and establish a largely asymptomatic persistent infection.^{22,155} SHFV was isolated from outbreaks of fatal hemorrhagic fever in macaque colonies¹⁸⁹ that were probably caused by inadvertent transmission by humans from African monkeys to macaques.

The unification of the previously unclassified arteriviruses was the direct result of the sequence analysis of their genomes, which revealed an intriguing relationship with coronaviruses and toroviruses (discussed in Chapter 28). Despite striking differences in genome size and virion structure, the genome organization and expression strategy of these viruses were found to be comparable and their replicase genes were postulated to share common ancestry⁵⁴ (e-Fig. 29.1). One of the most prominent features of their genome expression strategy, the generation of a nested set of subgenomic (sg) messenger RNAs (mRNAs), provided the basis for the name *Nidovirales*

(*L. nidus* = nest) that was given to the novel virus order comprising the arterivirus and coronavirus families in 1996. Subsequently, the order was further expanded with the invertebrate virus family *Roniviridae* and the genus *Bafinivirus*, which contains fish nidoviruses.⁸³ Most recently, the isolation of the first insect nidoviruses (proposed family name *Mesoniviridae*) was reported,^{140,249} yet again expanding the exceptional host range of the order *Nidovirales*. Furthermore, on the basis of its partial genome sequence, a novel nidovirus isolated from Australian possums (wobbly possum disease virus) appears to represent yet another nidovirus lineage, which is relatively closely related to the *Arteriviridae*.^{66a}

Nidoviruses represent a distinct lineage among plus-strand RNA viruses (e-Fig. 29.1). The complex evolutionary relationship between arteriviruses and nidoviruses with a much larger genome has been reviewed extensively elsewhere.⁸³ Related replicase genes and replication strategies have been combined with seemingly unrelated sets of structural protein genes. RNA recombination likely was an important factor in these evolutionary events and was also invoked to explain some internal rearrangements of arterivirus genomes.^{52,81,103}

VIRION STRUCTURE

Arteriviruses have been observed as spherical particles, 50 to 60 nm in diameter, and possess a relatively smooth, mostly featureless surface, which is likely explained by the small

ectodomains of the two major envelope proteins (Fig. 29.1; see^{20,68,175,182} and references therein). The nucleocapsid structure has long been assumed to be isometric, but recent cryo-electron tomography studies of PRRSV revealed a rather pleomorphic and “disorganized” core structure (average diameter 39 nm). These findings are clearly incompatible with an icosahedral core and suggest a resemblance to the nucleocapsid structure proposed for coronaviruses, a helical coil, or an even more loosely organized filamentous structure.^{61,182}

The buoyant density of arteriviruses is 1.13 to 1.17 g/cm³ in sucrose, and their sedimentation coefficient ranges from 214S to 230S. Virions are highly unstable in solutions containing low concentrations of nonionic detergents or at a pH other than 6.0 to 7.5, and quickly lose their infectivity when stored at temperatures higher than 4°C.

The arterivirus nucleocapsid structure (Fig. 29.2, e-Fig. 29.2) is composed of the 12.7 to 15.7 kb RNA genome and the nucleocapsid protein (N). The crystal structure for the capsid-forming C-terminal domain of PRRSV N⁵⁹; e-Fig. 29.2B) suggested that it represents a new class of viral capsid-forming domains, a hypothesis further supported by cryo-EM studies.

Based on studies with EAV and PRRSV, the lipid bilayer that surrounds the nucleocapsid is now presumed to contain seven envelope proteins (Table 29.1, Fig. 29.2), an unusually large number compared to other plus-stranded RNA viruses. In this chapter, we refer to the glycoproteins as “GPx”, where x indicates the number of the corresponding open reading frame

FIGURE 29.1. Electron micrographs of arterivirus particles. **A:** Transmission electron microscopic (EM) image of extracellular porcine reproductive and respiratory system virus (PRRSV) particles. **B:** Transmission EM image of an equine arteritis virus (EAV) particle budding from smooth intracellular membranes. **C:** Negatively stained, purified PRRSV particles. **D–E:** Cryo-EM of PRRSV particles in vitreous ice. **Panel D** shows a typical PRRSV particle with dimensions indicated. A possible spike protein complex and the striated appearance that most likely corresponds to the transmembrane domains of envelope proteins are visible. All bars are 25 nm. ORF, open reading frame; EAV, equine arteritis virus; aa, amino acid; GP, glycoprotein; nsp, nonstructural protein; LDV, lactate dehydrogenase-elevating virus; PRRSV, porcine reproductive and respiratory syndrome virus; SHFV, simian hemorrhagic fever virus.

^aMolecular characteristics were based on the sequences of the EAV-Bucyrus (European Molecular Biology Laboratory (EMBL) database accession number NC_002532), PRRSV-Lelystad (accession number M96262), LDV-P (accession number U15146), and the SHFV-LVR (accession number NC_003092).

^bNumbers of nsps are based on the known (EAV) or predicted (LDV/PRRSV/SHFV) replicase processing schemes as depicted in Figure 29.3 and e-Figure 29.6. Nsp8 is identical to the N-terminal domain of nsp9.

^cNot all proteins listed here have been identified in all four arterivirus particles.

^dAlternative names used in other (older) publications are indicated in brackets; SHFV protein nomenclature has been adapted with the most recent recommendations of the *Arteriviridae* study group of the International Committee on Taxonomy of Viruses (ICTV).⁶⁸

(ORF) in the genome (Table 29.1, Figs. 29.2 and 29.3). For simplicity, the GP encoded by ORF2a (PRRSV) or ORF2b (EAV/LDV) will be called GP2. Among arterivirus envelope proteins two major and five minor species are discriminated. The two major species, the nonglycosylated triple-spanning membrane protein M and GP5, form a disulfide-linked heterodimer^{57,69,174} (Fig. 29.2). By separately knocking out the expression of each of the structural proteins, it was established that

all major and minor structural proteins are required for the production of infectious progeny,^{131,232} with the possible exception of the recently discovered ORF5a protein.^{75,94}

Studies of GP2, GP3, and GP4, which form a heterotrimer in the virion^{230,232} (Fig. 29.2), have further highlighted their importance. Knockout mutants for minor structural protein genes produced noninfectious subviral particles consisting of GP5, M, N, and the genome RNA.^{231,232,243} When one of the

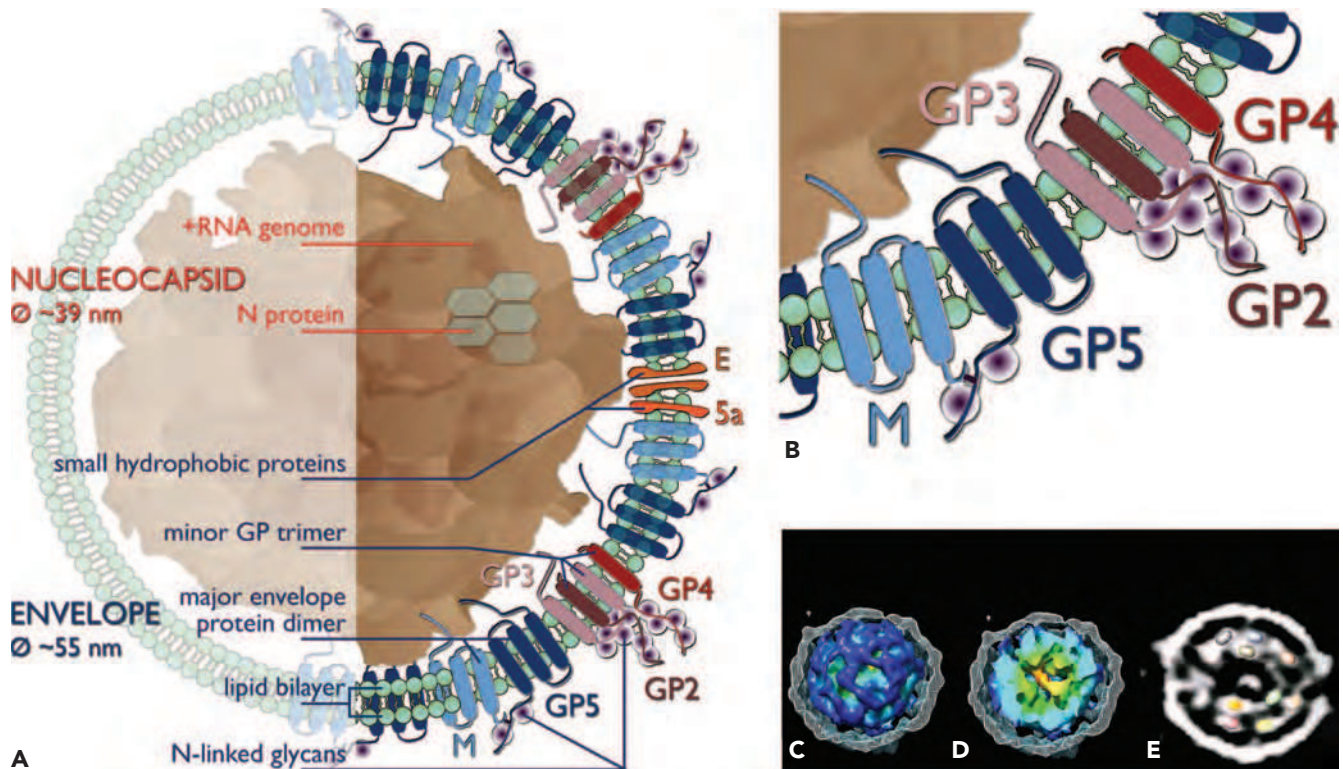

FIGURE 29.2. Arterivirus structure. **A:** The presumed location and topology of the envelope proteins GP2 to GP5, E, and M, the recently identified open reading frame (ORF)5a protein, and the N protein are shown (see also Table 29.1 and Fig. 29.3). The major envelope proteins GP5 and M form a disulfide-linked heterodimer. The minor glycoproteins GP2, GP3, and GP4 form a disulfide-linked heterotrimer. See **Panel B** for a close-up. In addition, also GP₂-GP₄ dimers (not depicted) have been identified in equine arteritis virus (EAV) particles. It should be noticed that not all proteins depicted here have been identified in all four arterivirus particles. **C–E:** Cryo-electron microscopy–based tomographic reconstruction of a porcine reproductive and respiratory syndrome virus (PRRSV) particle,¹⁸² revealing that the virion core is not solid, but consists of a two-layered shell that surrounds a hollow central cavity. **C:** Cutaway view of the internal core, obtained by peeling away the envelope (shown in mesh representation). The core, which is separated from the envelope by a 3-nm gap, appears disorganized and to consist of density strands that are bundled together into a ball. The data suggest a model for the core in which two layers of N dimers form a linked chain (see also **Panel E**). The core is shown as an isosurface, colored by the radius from the center of the particle (from red to blue). **D:** The core has been cut open to show the internal structure, including the central density (red-orange) typically seen in the tomograms. **E:** A 6.3-nm thick slab through the center of one PRRSV particle tomogram, with several copies of the crystal structure of the dimeric C-terminal domain of N, rendered at a comparable resolution and superimposed on the oblong densities in the core. (See also e-Fig. 29.2). (**C–E** from Spilman MS, Welbon C, Nelson E, et al. Cryo-electron tomography of porcine reproductive and respiratory syndrome virus: organization of the nucleocapsid. *J Gen Virol* 2009;90:527–535, with permission.)

components of the GP2-GP3-GP4 trimer or the small non-glycosylated envelope protein (E)¹⁷⁶ was lacking, the incorporation of the three minor GPs into virions was blocked.²³¹ Taken together, these data indicate that the basic protein scaffold of the arterivirus particle consists of the three major structural polypeptides, N, M, and GP5. Whether the incorporation of (genome) RNA is essential for the formation of the nucleocapsid structure, and which RNA sequences/structures specifically interact with N, remains to be established.

GENOME STRUCTURE AND ORGANIZATION

The arterivirus genome is a plus-stranded, 3′-polyadenylated RNA molecule, likely containing a cap structure at its 5′ end.¹⁶⁵

Full-length genomic sequences (see also Table 29.1) have been obtained for European and North American isolates of EAV, a large number of European, North American, and Asian PRRSV isolates, two LDV strains, and three SHFV isolates. The arterivirus replicase gene consists of the large ORFs 1a and 1b and roughly occupies the 5′ three-fourths of the polycistronic genome (Fig. 29.3). In contrast to the more conserved ORF1b region, the size of ORF1a is variable (encoding between 1,727 [EAV] and about 2,500 amino acids [PRRSV]), which largely explains the genome size differences encountered among arteriviruses. The region downstream of the replicase gene contains 8 to 11 relatively small genes, most of which have both 5′- and 3′-terminal sequences that overlap with neighboring genes. These genes encode mostly (or exclusively) structural proteins and are translated from sg mRNAs (see below). Their organization is

FIGURE 29.3. Arterivirus genome organization. The family prototype equine arteritis virus (EAV) is shown at the **top**. The replicase open reading frames (ORFs) 1a and 1b are followed by the gene encoding the E protein, three genes (ORFs 2a/b-4) encoding minor glycoproteins, the recently discovered ORF5a (presumably encoding a minor envelope protein), and the genes for the three major structural proteins GP5, M, and N (blue). The 3'-proximal region of the simian hemorrhagic fever virus (SHFV) genome carries a large insertion (highlighted in grey), containing four ORFs that may encode additional virion proteins. In the replicase ORFs, the positions corresponding to known or predicted cleavage sites in the encoded polyproteins is depicted. *Red arrowheads* represent sites cleaved by the nsp4 serine proteinase (S), the viral main protease. The papain-like proteinase domains (P) in the quite variable nsp1-nsp2 region and their (predicted) cleavage sites (*blue*) are also shown. The processing scheme of the SHFV nsp1 region remains to be elucidated. The three (putative) transmembrane domains (TM) in the ORF1a-encoded polyprotein are indicated (residing in nsp2, nsp3, nsp5). In ORF1b, the domains encoding the four most conserved nidovirus replicase domains are depicted: the RNA-dependent RNA polymerase (R), (putative) multinuclear zinc-binding domain (Z), RNA helicase (H), and the NendoU endoribonuclease domain (N).

generally well conserved in the arterivirus genome. An exception is the region downstream of the SHFV replicase gene, which contains four additional ORFs, comprising about 1.6 kb, which may have arisen from the duplication of ORFs 2a to 4.^{68,81}

THE ARTERIVIRUS REPLICATION CYCLE

Attachment and Entry

The entry of PRRSV and EAV requires a low pH, suggesting that it occurs via the standard endocytic route^{101,137,141} (Fig. 29.4). Clathrin heavy-chain knockdown suppressed EAV infection¹⁴¹ and electron microscopy revealed arterivirus particles contained in relatively small vesicles that appeared to be clathrin coated.^{100,101}

The host factors required for arterivirus entry have been studied in detail only for PRRSV (e-Fig. 29.3). Several viral and cellular players have been implicated in binding, entry, and uncoating, although their exact roles remain to be defined in more detail (for recent reviews see 203,224). Sialoadhesin (or sialic acid-binding immunoglobulin [Ig]-like lectin 1 [CD169]; 216), a macrophage-restricted membrane protein, mediates the

internalization of the virus by porcine alveolar macrophages (PAMs), the primary target cells of PRRSV.^{64,66} In addition, glycosaminoglycans (heparan sulfate) on the cell surface⁵¹ and sialic acids on the virion surface⁵⁰ were implicated in the initial binding step. It is believed that the virus initially binds heparin-like molecules on the cell surface and that subsequently internalization via clathrin-mediated endocytosis is triggered by the interaction of CD169 with sialic acids on the ectodomains of the GP5/M dimer.²⁰⁴ Expression of porcine CD169 in nonsusceptible cell lines can mediate PRRSV internalization, but not disassembly and productive infection,²¹⁶ indicating that additional factors must be required for successful infection. This notion is further supported by the fact that MARC-145 cells, which are commonly used to grow PRRSV, do not express CD169 on their surface.⁶⁴ In particular CD163, a member of the scavenger receptor cysteine-rich (SRCR) family, was implicated in the early stages of PRRSV infection.²⁶ Although normally a macrophage-specific antigen, CD163 is aberrantly expressed on MARC-145 cells, possibly explaining their unique susceptibility to PRRSV infection among nonengineered cell lines. Expression of CD163 from various species rendered a variety of nonpermissive cell lines susceptible to PRRSV infection, in the

FIGURE 29.4. Overview of arterivirus replication. Following entry by receptor-mediated endocytosis and release of the genome into the cytosol, genome translation yields the pp1a and pp1ab replicase polyproteins (shown as yellow bars). Following polyprotein cleavage by multiple internal proteases, the viral nonstructural proteins assemble into a replication and transcription complex (RTC) that engages in minus-strand RNA synthesis. Both full-length and subgenome-length minus strands are produced, with the latter templating the synthesis of subgenomic messenger RNAs (mRNAs) required to express the structural protein genes in the 3'-proximal quarter of the genome. Ultimately, novel genomes are packaged into nucleocapsids that become enveloped by budding from smooth intracellular membranes, after which the new virions leave the cell by following the exocytic pathway. (See text for more details.)

absence of detectable CD169 expression. It was postulated that in PAM, CD169 and CD163 work together, with the former serving as receptor for internalization and the latter playing a key role in virus uncoating and genome release, which are thought to occur in association with the early endosome, following its acidification²¹¹ (e-Fig. 29.3).

Which virion proteins direct the fusion between viral envelope and endosomal membrane remains one of the key questions to be addressed. A role for the minor glycoproteins in arterivirus receptor recognition and tropism has not been rigorously excluded.⁴⁴ In fact, recent data show that a chimeric PRRSV carrying E, GP2, GP3, and GP4 of EAV acquired the broad tropism for cultured cells that is typical of the

latter virus.¹⁹³ These findings are in line with the previously observed phenotypes of recombinant viruses in which the GP5 or M ectodomain was replaced, which did not result in an altered tropism in cell culture.^{60,219} These studies, together with the identification of several other host factors as potential "PRRSV entry mediators",^{203,224} illustrate that several questions and controversies regarding arterivirus entry remain to be addressed.

Genome Translation and Replication

The arterivirus replication cycle (Fig. 29.4) is presumed to be entirely cytoplasmic, despite the fact that at least two viral proteins are (in part) targeted to the nucleus (see below). The

incoming genome is translated into the two large replicase polyproteins pp1a (1,727 to 2,502 amino acids) and pp1ab (3,175 to 3,959 amino acids), which comprise all functions required for viral RNA synthesis.¹³¹ Despite the relatively large 5' non-translated region (NTR), translation presumably initiates following “conventional” ribosomal scanning of the genomic 5' NTR.²⁰⁶ ORF1b translation requires a -1 ribosomal frame shift (estimated efficiency of 15% to 20%) just before ORF1a translation is terminated⁵⁴ (Fig. 29.3). The ORF1a/1b overlap region contains two signals that are assumed to promote this event: a so-called “slippery” sequence, which is the actual ribosomal frame shift site, and a downstream RNA pseudoknot structure.

Following proteolytic processing of the replicase polyproteins, a complex for viral RNA synthesis is formed that generates

a genome-length minus strand (or “anti-genome”), the template for genome replication. In addition, a complex transcription mechanism operates to produce complementary nested sets of sg-length minus-strand RNAs and sg mRNAs⁵⁵ (see below and Fig. 29.5). The RNA signals involved in arterivirus genome replication remain to be studied in detail. The coding regions of the genomes are flanked by 5' and 3' NTRs of 156 to 221 and 59 to 117 nucleotides, respectively. However, natural and synthetic defective interfering RNAs of EAV invariably require at least 300 nucleotides from both genome termini for efficient replication, indicating that replication signals extend into the coding sequences.^{130,198} Likewise, in the case of PRRSV, a so-called “kissing interaction” between the loop sequences of RNA hairpin structures in the 3' NTR and the N protein gene was found to be crucial for viral RNA synthesis.²¹⁸

FIGURE 29.5. Arterivirus RNA synthesis. Model for arterivirus (and coronavirus) replication and transcription^{146,166–167,168} using a hypothetical arterivirus genome encoding three subgenomic messenger RNAs (mRNAs). The top half of the scheme depicts the replication of the genome by the viral RNA-dependent RNA polymerase (RdRp) complex, which requires a full-length minus-strand intermediate (anti-genome). The bottom half illustrates how minus-strand RNA synthesis can be interrupted at a body transcription-regulating sequence (TRS) (+B), after which the nascent minus strand, having a body TRS complement (-B) at its 3' end, is redirected to the leader TRS (+L) near the 5'-end of the genome. This +L sequence is thought to be “presented” for base pairing by a viral RNA structure, the leader TRS hairpin (LTH), that is critical for subgenomic RNA synthesis. Guided by a base-pairing interaction between the complementary -B and +L sequences, RNA synthesis is resumed to add the complement of the genomic leader sequence (anti-leader) to each nascent subgenome-length minus strand. Subsequently, the subgenome-length minus strand RNAs each serve as template to produce one of the subgenomic mRNAs. The RdRp complexes engaged in replication and transcription may be (partially) different. For example, in the equine arteritis virus (EAV) model, nsp1 has been identified as a regulatory factor that is dispensable for replication but required to regulate the accumulation levels of the different subgenomic RNAs, most likely by controlling a step during minus strand RNA synthesis. See text for more details.

Using a combination of approaches, detailed RNA secondary structure models were developed for the EAV 5' and 3' NTRs. In the 5' NTR, a region involved in translation, replication, and transcription,²⁰⁵ (e-Fig. 29.4B), one domain in particular was found to be crucial for sg RNA production (see below). This so-called “leader TRS [transcription-regulating sequence] hairpin” (LTH) is potentially conserved in the 5' NTR of all arteriviruses (e-Fig. 29.4C). The importance of the other structural features of the EAV 5' NTR and, for example, their involvement in RNA–protein interactions, remains to be investigated because few of these elements are conserved in other arteriviruses.²⁰⁵ A possible exception is EAV hairpin C (termed SL2 in PRRSV; 115) that was reported to be crucial for PRRSV replication and subgenomic RNA synthesis in particular (e-Fig. 29.4C).

The 3' NTR of the arterivirus genome does not contain obviously conserved primary sequences. For EAV, the 3'-terminal CC motif immediately upstream of the poly(A) tail plays a critical role in viral RNA synthesis.¹⁵ Furthermore, a stem-loop structure near the 3'-terminus of the EAV genome is also required for RNA synthesis¹⁴ (e-Fig. 29.5A) and its loop was implicated in an essential pseudoknot interaction with an upstream stem-loop structure residing in the N protein gene.¹⁵ This conformation was predicted to be conserved in all arteriviruses and proposed to constitute a molecular switch that could regulate the specificity or timing of viral (minus strand) RNA synthesis (e-Fig. 29.5B).

Various proteins from MA-104 cells bind to arterivirus-derived RNA sequences,^{90,122} and the *in vitro* RNA-synthesizing activity of semi-purified EAV replication and transcription complexes depends on the presence of a soluble host protein of 59 to 70 kD, which remains to be identified.²¹²

Synthesis and Translation of Subgenomic mRNAs

One of the hallmarks of the replication cycle of arteriviruses (and other nidoviruses) is the synthesis of a 3'-co-terminal nested set of sg mRNAs (Fig. 29.5) from which the genes in the 3' end of the genome are expressed. In the case of arteriviruses, all these genes encode structural proteins. Arterivirus sg mRNAs also have a common 5' end, the so-called “leader sequence,” which is derived from the 5' end of the genome.⁵⁵ This property is shared with coronaviruses, but—remarkably—not with some other nidoviruses (toroviruses and roniviruses; for reviews, see 83,146,168). Supported by the presumed common ancestry of the arterivirus and coronavirus replicase genes, leader-to-body fusion during arterivirus sg RNA synthesis was proposed to rely on a mechanism of discontinuous RNA synthesis similar to that previously proposed for coronaviruses. In both virus groups, short conserved TRSs are present at the 3' end of the leader sequence (“leader TRS”) and at the 5' end of each of the transcription units specifying a sg mRNA “body” (“body TRS”; reviewed in 146,168,175). The observation that arterivirus-infected cells contain a nested set of sg-length minus-strand RNAs, complementary to the sg mRNAs, is another important parallel with coronaviruses.^{30,53}

With the exception of the smallest species, the arterivirus sg mRNAs are structurally polycistronic, but most of them are assumed to be functionally monocistronic. Notable exceptions are mRNAs 2 and 5 (in EAV, LDV, and PRRSV; Fig. 29.3), which are functionally bicistronic transcripts from which the partially overlapping gene sets E/GP2 and ORF5a/GP5 are

expressed.^{75,94,176} The mRNAs tentatively numbered 4 and 6 are thought to be used to translate the corresponding SHFV gene sets, and also mRNA2 of this virus was proposed to be functionally bicistronic.⁸¹

A substantial number of models for coronavirus and arterivirus sg mRNA synthesis have been proposed and reviewed extensively (see also Chapter 28; 146,168,175, and references therein). The detection of sg-length minus strands indicated that the discontinuous step in sg RNA synthesis likely occurs during minus-strand RNA synthesis. This concept was subsequently supported by data from biochemical and genetic studies with coronaviruses and arteriviruses and resulted in a model (Fig. 29.5; e-Fig. 29.4) in which discontinuous extension of minus-strand RNA synthesis yields sg-length minus-strand templates for sg mRNA synthesis.^{166,168}

Direct proof for base-pairing between leader TRS and antibody TRS was obtained from reverse genetics studies using an EAV infectious complementary DNA (cDNA) clone.^{147,214} The mechanism by which the transcriptase is translocated between the body and leader TRS in the genomic template, a step that may resemble copy-choice RNA recombination,^{19,147,214} remains to be elucidated. Arterivirus sg RNAs are produced in nonequimolar, but relatively constant amounts, thus providing a mechanism to regulate the expression of the various structural protein genes. EAV reverse genetics studies have rigorously demonstrated that transcription depends on duplex formation between leader TRS and antibody TRS and that—in general—the relative amount of sg mRNA correlates with the calculated stability of this duplex.^{147,148,214} Sequences flanking the body TRS, the relative order and/or location of body TRSs in the genome, and possibly also higher order RNA structure were also shown or postulated to influence transcription.¹⁴⁵ Structural studies on the 5'-proximal part of the EAV genome²⁰⁵ placed the leader TRS in a single-stranded loop of the structure referred to as the “leader TRS hairpin” (or LTH; e-Fig. 29.4B,C), which was characterized as a critical player in transcription.²⁰⁶

At the protein level, transcription-specific functions have been attributed to several replicase subunits, in particular non-structural protein 1 (nsp1) and nsp10, for which mutations were described that resulted in the (near) complete inactivation of sg mRNA synthesis.^{138,196,198,208} EAV nsp1 controls the accumulation levels of viral genome and individual sg mRNAs in the infected cell by determining the levels at which the minus-strand templates for each of these molecules are produced.¹³⁸ An N-terminal zinc finger (ZF) domain was implicated in this function, but also other nsp1 domains appear to be important. Mutagenesis of nsp1 triggered the evolution of numerous nsp1 pseudorevertants with compensatory mutations that invariably rescued both balanced EAV mRNA accumulation and efficient virus production.¹³⁸ In the case of PRRSV, where nsp1 is internally cleaved into nsp1 α and nsp1 β , the ZF-containing nsp1 α subunit is presumed to fulfill a similar role in transcription regulation.¹⁰²

Arterivirus Proteinases and Posttranslational Processing of the Replicase

The proteolytic maturation of the arterivirus pp1a and pp1ab replicase polyproteins involves the rapid autoproteolytic release of three or two N-terminal nsps and the subsequent cleavage of the remaining part of both polyproteins by the viral nsp4 “main protease.” The posttranslational processing of the

replicase polyproteins has been studied most extensively for EAV (see 202,248, and references therein; e-Fig. 29.6A,B) for which pp1a and pp1ab are cleaved 8 and 11 times, respectively, by three ORF1a-encoded proteinases (see below). In combination with the ORF1a/1b ribosomal frame shift, this yields 13 processing end products (named nonstructural protein [nsp] 1 to 12, including nsp7 α and nsp7 β ; Fig. 29.3; e-Fig. 29.6E). Of these, nsp1-8 are generated from ORF1a, whereas nsp10-12 are entirely ORF1b-encoded and nsp9, due to the ribosomal frame shift consisting of a small, ORF1a-encoded N-terminal domain (identical to nsp8) and a large C-terminal part that is encoded by ORF1b and includes the viral RNA-dependent RNA polymerase (RdRp) domain. EAV reverse genetics studies with cleavage site mutants underscored the critical importance of replicase polyprotein processing for virus replication.^{202,209} The nsp3-8 region of pp1a (and likely also pp1ab) is subject to two alternative processing cascades, with the “major pathway” requiring an interaction with nsp2 as a cofactor, to mediate cleavage of the nsp4/5 site²²² (e-Fig. 29.6D).

The three EAV proteinase domains in nsp1, nsp2, and nsp4^{474,175,248} (e-Fig. 29.6) and their corresponding cleavage sites are well conserved in the other arteriviruses (Fig. 29.3). EAV nsp1 and nsp2 both contain a papain-like proteinase domain (PLP; formerly referred to as PCP or CP for [papain-like] cysteine protease) that mediates their rapid release from the polyprotein,¹⁷⁸ whereas nsp4 includes a chymotrypsin-like serine proteinase (SP), the arterivirus main proteinase.¹⁸⁰ PRRSV and LDV, in addition to having homologs of these three EAV proteinases, possess a fourth nonstructural proteinase,⁵² which mediates the rapid release of an additional N-terminal cleavage product. This PLP α possibly is a duplication of the proteinase (PLP β) present in the C-terminal domain of EAV nsp1 and appears to have become inactivated in EAV.⁵² The sequence analysis of the SHFV nsp1 region revealed an even more complex situation, with an array of three potential PLP domains present in the 480-residue region upstream of the (predicted) nsp1/nsp2 junction. The nsp4 SP combines the His-Asp-Ser catalytic triad of classical chymotrypsin-like proteinases with the substrate specificity of the so-called 3C-like cysteine proteinases, a subgroup of chymotrypsin-like enzymes named after the picornavirus 3C proteinases. Specific residues in the substrate-binding region of the SP are assumed to determine its specificity for cleavage sites containing Glu (or sometimes Gln) as the P1 residue and mainly Gly, Ala, or Ser at the P1' position. Nine such sites were identified in EAV pp1a/pp1ab, and they were all found to be conserved in the other family members.^{175,202,248}

Nsp4 structures have been obtained by x-ray crystallography for both EAV and PRRSV^{11,195} (e-Fig. 29.7). The protein consists of three domains, with domains I and II forming the typical chymotrypsin-like two- β -barrel fold of the SP. The C-terminal domain III is dispensable for proteolytic activity and may be involved in fine-tuning replicase polyprotein cleavage.^{200,201} Recent structural studies also elucidated the structures of PRRSV nsp1 α ¹⁸⁶ and nsp1 β ,²³⁸ including their respective PLP domains (e-Fig. 29.7), which—in line with previous studies—were both confirmed to employ a Cys-His tandem as active site residues. Both PLP α and PLP β appear to act exclusively *in cis* and the two structures indeed revealed the presence of the C-terminal region of the proteins in the PLP substrate-binding pocket, suggesting an intramolecular cleavage mechanism that

would preclude further proteolytic reactions. Both nsp1 α and nsp1 β of PRRSV have also been implicated in evasion of the host's immune response (see below), but this was most directly demonstrated for the PLP that resides in the N-terminal domain of the highly variable nsp2 subunit. This PLP2, which possesses both *cis* and *trans* cleavage activities,^{86,179} not only directs the critical cleavage of the nsp2/3 site in pp1a and pp1ab, but is also able to remove ubiquitin (Ub) and Ub-like modifiers like ISG15 from yet-to-be-identified substrates in the infected cell.²¹³ The protein is distantly related to the ovarian tumor domain (OTU) family of deubiquitinating enzymes.^{76,123,187}

Replicase Proteins and the Replication Complex

Although accelerated by research efforts following the emergence of severe acute respiratory syndrome (SARS)-coronavirus, the functional dissection of the complex array of nidovirus nonstructural protein functions is still in its infancy. Even the arterivirus replicase polyproteins are of extraordinary size and complexity, despite their twofold smaller size compared to nidoviruses with larger genomes like coronaviruses and roniviruses. Therefore, future studies will undoubtedly reveal both novel similarities and differences between these two groups. In arteriviruses, with the notable exception of the role of nsp1 in sg mRNA synthesis (see above), the ORF1a-encoded functions mainly appear important for the regulation of replicase gene expression (by proteolytic processing; see above) and formation of the membrane-anchored “scaffold” for the replication/transcription complex. The ORF1b-encoded proteins, on the other hand, appear to be more directly involved in viral RNA synthesis.

Except for the proteins from the nsp1 region,^{31,197} all replicase subunits localize to the perinuclear region of the infected cell (e-Fig. 29.8A–D; 207), where they are associated with intracellular membranes that are derived from the endoplasmic reticulum (ER). Upon arterivirus infection, these host cell membranes are modified into vesicular double-membrane structures that presumably carry the viral replication complex (e-Fig. 29.9A–F).^{149,177,212} The formation of closely paired membranes and double membrane vesicles (DMVs) is a typical feature of arterivirus-infected cells described many years ago.^{18,184,234} Recent electron tomography studies of EAV-infected cells revealed that these structures are in fact interconnected and form a network of modified ER⁹⁹ (e-Fig. 29.9E). Biochemical and electron microscopy studies have implicated ORF1a-encoded subunits that contain hydrophobic, probable trans-membrane domains (in particular nsp2, nsp3, and nsp5; e-Fig. 29.6C) in the formation of these membrane structures.^{71,149,158,177,207}

Replicase ORF1b is the most conserved part of the arterivirus genome and encodes the core enzymes for viral RNA synthesis—RdRp (nsp9) and helicase (nsp10).^{54,83,140} Recombinant EAV nsp9 is able to initiate RNA synthesis *de novo* in the absence of other viral or cellular proteins, but could not utilize sequences derived from the 3' end of the viral genome as a template,¹³ suggesting additional requirements for its activity *in vivo*. The predicted NTP binding and superfamily 1 helicase activities of arterivirus nsp10 were corroborated by *in vitro* assays with recombinant nsp10. These also revealed the 5'-to-3' polarity of the unwinding reaction, a property shared with coronaviruses,^{12,169} although it has not been reconciled with the protein's presumed role in unwinding local double-stranded

RNA structures that might hinder the RdRp during viral RNA synthesis, which proceeds in the opposite direction. As in all nidoviruses, the helicase is linked to an N-terminal zinc-binding domain that might assist the proper folding of nsp10 and/or mediate interactions of the protein with its substrate RNAs. This domain was also implicated in a remarkable transcription-specific defect.^{208,210}

Advanced bioinformatics studies provided the first evidence to suggest that nsp11, and its coronavirus homolog nsp15, contain a nidovirus-specific endoribonuclease activity (NendoU; 173). Subsequently, this prediction was experimentally verified in biochemical assays for recombinant coronavirus nsp15⁹¹ and EAV nsp11.¹³⁹ In the meantime, the site-directed mutagenesis of key NendoU residues had been found to exert pleiotropic effects on EAV RNA synthesis, including a complete block in some of the mutants and more moderate effects in others.¹⁵⁷ The exact function of the NendoU domain, a genetic marker of vertebrate nidoviruses,¹⁴⁰ remains to be elucidated, and in particular its substrate specificity in the infected cell is an enigma. Recombinant NendoU-containing proteins exhibit broad substrate specificity *in vitro*, processing both single-stranded and double-stranded RNA substrates 3' of pyrimidines.¹³⁹ However, in the context of the infected cell, NendoU activity or substrate specificity may be controlled via specific protein–protein interactions or compartmentalization of the enzyme as part of the membrane-associated replication and transcription complex.

The final ORF1b-encoded replicase subunit of arteriviruses, nsp12, has not been the subject of experimental studies, and sequence comparisons did not suggest a function or a relationship to any other known protein family.

Assembly and Release

EAV N partially co-localizes with the complex for viral RNA synthesis (197; e-Fig. 29.8D). Because N is not required for replication or transcription,^{131,208,232} this suggests that genome encapsidation may occur (or begin) at the site of viral RNA synthesis. Recent electron tomography studies of EAV-infected cells revealed a network of N-containing sheets and tubules in close vicinity of the membrane structures where viral RNA synthesis is thought to occur, but the functional significance of these N structures remains to be studied in more detail.⁹⁹

Arteriviruses acquire their envelope by budding of preformed nucleocapsids into the lumen of the smooth endoplasmic reticulum and/or the Golgi complex^{121,184,234} (e-Fig. 29.8E–F and e-Fig. 29.9G–H). Most arterivirus envelope proteins are retained in intracellular membranes (e-Fig. 29.8E–F), and the formation of the GP5-M heterodimer is a primary determinant of virus budding.^{231,232,243} The transport of GP5 and M to the Golgi complex appears to depend on complex formation and correlates with the production of infectious virus.^{60,174,219} After budding, virions accumulate in intracellular vesicles, which are transported to the plasma membrane and release the progeny virus.

Major Structural Proteins

The three major structural proteins GP5, M, and N are encoded—in this order—by the three most 3'-proximal ORFs in the arterivirus genome (Fig. 29.3 and Table 29.1). N is small (12 to 15 kD) and contains many basic residues, in particular in its presumably disordered N-terminal domain, which

is thought to interact with the genomic RNA during nucleocapsid assembly.^{59,61} The C-terminal “capsid-forming” half of N forms dimers in solution and is the basis for a proposed “nidovirus nucleocapsid fold” that is also encountered in the much larger coronavirus N protein.⁶¹ The EAV and PRRSV N proteins are phosphorylated.^{56,235} In the case of PRRSV N, phosphoserines mapped to both the RNA binding domain and the capsid-forming domain where they may modulate nucleic acid binding activity or protein–protein interactions.²³⁵

The nonglycosylated M protein (16 to 20 kD) resembles the coronavirus M protein in that its N-terminal half presumably traverses the membrane three times,^{56,70,127} resulting in an N_{exo}-C_{endo} configuration with a short ectodomain of only 10 to 18 residues exposed at the virion surface. One of the membrane-spanning fragments is thought to function as an internal signal sequence. The arterivirus M protein forms disulfide-linked heterodimers with the 24 to 54 kD GP5, a step probably driven by the formation of a disulfide bridge between a conserved Cys residue in the M ectodomain and a Cys residue in the GP5 ectodomain.^{57,69,174} EAV GP5-M heterodimers are thought to be essential for virus assembly, possibly by inducing the membrane curvature required for virus budding.^{57,60,174}

Despite considerable differences in primary structure, the major GPs of arteriviruses (GP5) share common structural features. They contain an N-terminal signal sequence that is assumed to be cleaved from a short ectodomain. The central hydrophobic region probably spans the membrane three times and is followed by a cytoplasmic domain of 50 to 75 amino acids. In the case of LDV and PRRSV, the ectodomain is only about 30 residues long and contains one to three N-linked glycans.^{70,127} The ectodomain of EAV GP5 is 95 residues long and usually possesses a single N-linked polylactosamine side chain,⁵⁶ although in some strains an additional N-linked glycan is present. In addition, in the case of LDV, GP5 glycosylation occurs by the addition of variable numbers of lactosamine repeats.¹¹⁰ Nonneuropathogenic and neuropathogenic strains typically contain three and one polylactosaminoglycan chain(s), respectively (see below).

Minor Structural Proteins

The minor arterivirus GP encoded by ORF2a (PRRSV) or ORF2b (EAV/LDV) is a conventional class I integral membrane protein with an N-terminal signal peptide, a C-terminal transmembrane segment, and 1 to 4 potential N-glycosylation sites in its ectodomain. GP2 occurs in EAV-infected cells in a variety of monomeric conformations and in complex with other minor GPs.^{228,231} Complex formation is a prerequisite for incorporation into virions.^{231,232} Cysteine residues in the EAV GP2 ectodomain form both intramolecular and intermolecular cysteine bridges, the latter involving a cysteine in the ectodomain of GP4, which also is a typical class I integral membrane protein.²²⁸

GP3 is a heavily glycosylated integral membrane protein with an uncleaved N-terminal signal sequence and a hydrophobic C-terminal domain, suggesting the protein is anchored in the membrane with both termini.^{87,229} Like GP2 and GP4, EAV GP3 localizes to the endoplasmic reticulum, both in infected cells and in expression systems.²²⁹ Following initial conflicting reports, PRRSV GP3 is now firmly believed to be present in virions,^{48,232} which is also in line with the data obtained for EAV. Following virus release, GP3 becomes disulfide-linked to

the GP2-GP4 heterodimers, and this postassembly maturation event yields a complex of three covalently bound minor GPs. As a result, EAV particles contain both GP2-GP4 heterodimers and GP2-GP3-GP4 heterotrimers.^{230,231}

Like GP2, GP4 is a predicted class I membrane protein with a cleaved signal sequence and multiple N-glycosylation sites in its ectodomain.^{129,215,229} Little is known about the properties or function of GP4, apart from the oligomerization described above and the finding that GP4 may be responsible for an interaction of the GP2-GP3-GP4 trimer with GP5.⁴⁴ Recent reverse genetics studies with PRRSV mutants lacking specific glycans in GP2, GP3, and GP4 documented the general importance of these posttranslational modifications for virus viability and interactions with CD163.⁴⁵

The higher order structure of the small E protein is unknown, but this protein is essential for virus infectivity¹⁷⁶ and may in fact be associated with trimer of minor GPs.²³¹ The protein has been proposed to oligomerize and form an ion channel that could play a role during viral entry.¹⁰⁶ Furthermore, its N-terminus contains a myristoylation signal that is conserved across arteriviruses and is functional in EAV and PRRSV. A block of the fatty acid addition was not lethal, but knockout mutants were crippled and displayed a small-plaque phenotype.^{63,190}

Finally, another gene encoding a small generally hydrophobic protein was recently identified in EAV⁷⁵ and PRRSV.⁹⁴ Bioinformatics analyses revealed a potential open reading frame (ORF5a) overlapping the 5' end of ORF5, and the ORF5a protein was identified in purified PRRSV virions. EAV reverse genetics revealed that the protein is not essential, but knockout mutants showed a significant reduction of progeny titers.

Replication in Cultured Cells and Host Cell Interactions

With the exception of EAV, arteriviruses have a very restricted host specificity (for reviews, see 155, 175 and references therein). LDV grows in primary cultures of mouse macrophages, but not in macrophage or other cell lines. In addition to primary macrophages from their respective hosts, SHFV and PRRSV also replicate in cell lines of African green monkey kidney cells (MA-104 and derivatives thereof, like the MARC-145 cell line discussed above). EAV replicates efficiently in primary cultures of horse macrophages and kidney cells, and—remarkably—also in a variety of cell lines such as baby hamster kidney, rabbit kidney, and African green monkey kidney and mouse C2C12 cells.²⁴⁵

One-step growth experiments have shown that maximum progeny virus titers are generally released by 10 to 15 h postinfection. The maximum titers obtained in cell culture are 10^6 to 10^7 tissue culture infectious dose (TCID)₅₀/ml for PRRSV, but may exceed 10^8 PFU/ml for EAV and SHFV.^{155,175} In general, arterivirus infection of macrophages and cell lines is highly cytotoxic, resulting in rounding of the cells and detachment from the culture plate surface, although recently a model for persistent noncytopathic infection with EAV in human HeLa cells was established.²⁴⁵

Arteriviruses interact with a variety of host factors and mechanisms. For example, arteriviruses were claimed to induce or modulate apoptosis in cell lines and/or cultured macrophages.^{3,39,185,251} PRRSV also induces apoptosis in germ cells *in vivo*.¹⁸⁸ In both macrophages and MARC-145 cells, PRRSV stimulated antiapoptotic pathways early in infection, but late in infection cells died from caspase-dependent apoptosis, culminating in secondary necrosis.³⁹

Despite the cytoplasmic replication cycle of arteriviruses, some viral proteins are directed (in part) to the nucleus of infected cells (e-Fig. 29.8), specifically nsp1 (see above) and the N protein. A nuclear localization signal, for interaction with the nuclear transporters importin α and β , was identified at positions 41–47 of PRRSV N,¹⁶⁴ which—like its EAV counterpart—accumulates in the nucleoli of infected cells.^{164,197} Remarkably, a block of CRM1-mediated nuclear export with the drug leptomycin B resulted in the nuclear accumulation of EAV N, indicating that the protein apparently shuttles between cytoplasm and nucleus before playing its role in cytoplasmic virus assembly.¹⁹⁷ Various nuclear host proteins interact with PRRSV N (reviewed by 240), including fibrillarin, nucleolin, and poly(A)-binding protein, but the functional implications of these findings remain to be unraveled. Using reverse genetics, a knockout mutation for the nuclear localization signal of PRRSV N was engineered and yielded a viable, although seriously attenuated, mutant virus.¹⁰⁵ Compared to the wild-type control, pigs infected with this mutant virus showed reduced viremia and significantly higher neutralizing antibody titers.

PATHOGENESIS AND PATHOLOGY OF ARTERIVIRUS INFECTIONS

The natural host range of arteriviruses is restricted to horses and donkeys (EAV), pigs (PRRSV), mice (LDV), and several genera of African and Asian monkeys (SHFV). Recent outbreaks of equine viral arteritis in New Mexico, United States (2006) and Normandy, France (2007) increased the interest of horse owners and veterinarians in EAV treatment and vaccines. Highly virulent PRRSV variants, causing the so-called “porcine high fever disease,” emerged in China in 2006 and still continue to cause problems in this and surrounding countries.^{107,194,246}

Site of Primary Replication, Spread, and Cell and Tissue Tropism

Macrophages appear to be the primary target cell for all arteriviruses.¹⁵⁵ Cell surface molecules mediating entry into these cells are only known for PRRSV and have been discussed above. Following respiratory transmission, EAV initially replicates in lung macrophages and endothelial cells.^{5,88} The virus then spreads to draining lymph nodes, from where it becomes disseminated throughout the body via the circulation. By the third day of infection, a viremia has developed and virus can be isolated from practically all tissues.

Reported primary target cells for PRRSV replication are fully differentiated porcine lung alveolar macrophages and other cells of the monocyte/macrophage lineage including pulmonary intravascular macrophages, subsets of macrophages in lymph nodes and spleen, and intravascular macrophages of the placenta and umbilical cord.^{65,104,191} After spreading through the circulation, PRRSV replicates persistently in tonsils, lungs, and lymphoid organs (reviewed in 192).

IMMUNE RESPONSES

Several arteriviruses cause persistent infections despite the presence of an adaptive immune response. Neither neutralizing antibodies nor effective helper and cytolytic T lymphocytes are

able to control virus replication in these persistently infected animals. Therefore, arteriviruses must have developed strategies to evade immune responses, underpinning the importance of studying immunity in natural and experimental infections in order to enhance our understanding of the underlying mechanisms. For a more detailed overview of the immune response to arterivirus infection, the reader is also referred to a variety of other review articles,^{5,43,114,125,134} and references therein.

Innate Immune Response

It is rather unclear at present which pattern-recognition receptors (PRRs) of the innate immune system recognize arteriviruses during infection of different cell types. Several reports have suggested or speculated on the involvement of toll-like receptor 3 (TLR3) during infection of PRRSV in macrophages and lymphoid tissue (see 43 and references therein). A study with EAV in knockout mouse embryonic fibroblasts suggested that of the cytosolic retinoic acid inducible I-like receptors (RLRs), melanoma differentiation-associated gene (MDA5) is predominantly involved in the recognition of this virus.²¹³ Experimental infection of TLR7^{-/-} mice with LDV revealed the importance of this TLR expressed by plasmacytoid dendritic cells (pDCs) for the induction of type I interferon (IFN) and the activation of lymphocytes during LDV infection.¹

In vitro studies using alveolar and blood-derived macrophages demonstrated that tumor necrosis factor (TNF)- α and other proinflammatory cytokines are induced following infection with virulent EAV strains.^{5,132} In the case of PRRSV, it is generally believed that a rather weak innate immune response is induced (see 5,43,132,134, and references therein). Induction of TNF- α as well as IFN- α by PRRSV and also the sensitivity to these innate cytokines, seems to depend on the isolate. Chen et al.³³ suggested that this may at least in part relate to variability in nsp2, in which abundant changes and deletions were found among different isolates, which seem to influence host immune responses. Multiple studies reported that PRRSV induces interleukin 8 (IL-8), whereas the induction of IL-6 as well as that of IL-10 is debated (see also below; 43, and references therein).

LDV induced natural killer (NK) cells in infected mice and as a consequence a large increase in serum IFN- γ was observed, but these responses were unable to control LDV replication.¹²⁴ LDV also elicits IFN- α induction through TLR7 activation in plasmacytoid dendritic cells, but the virus is not sensitive to a systemic IFN- α response in mice.¹

Humoral Immune Response

Antigenic cross-reactivity between different arterivirus species has not been demonstrated, with the exception of antibodies directed against the single linear neutralization site of LDV GP5, which do not only neutralize LDV, but also PRRSV.¹⁵⁶ Sera from EAV-infected horses recognize N, M, GP5, and GP2.^{34,118} In addition, antibodies against the nonstructural proteins nsp2, nsp4, nsp5, and nsp12 were found in experimentally or persistently infected horses, whereas animals vaccinated with a modified live virus (MLV) vaccine against EAV produced antibodies against nsp2 and nsp12, and much less against nsp4 and nsp5.⁷⁹ PRRSV-infected pigs produce antibodies directed against the structural proteins GP2 to GP5, M, and N, with the antibodies recognizing N being detected earliest and most abundantly.^{43,112,128} The early humoral response against PRRSV also

includes antibodies against nsp1 and particularly nsp2, which develop to titers as high as those of the anti-N antibodies.⁹⁵

It has been proposed that LDV- and PRRSV-specific antibodies contribute to antibody-dependent enhancement (ADE) of infection.^{25,241,242} For PRRSV, certain nonneutralizing epitopes in the N and GP5 proteins induce antibodies that seem responsible for ADE through opsonization, leading to enhanced internalization of the virus into macrophages.^{27,43,125}

Neutralizing antibodies (NAs) in arterivirus-infected animals are predominantly directed to the major glycoprotein GP5.^{6,24,34,82,143,153,154} The neutralization site in EAV, PRRSV, and LDV GP5 was mapped to the ectodomain of the protein.^{8,34,110,154} For EAV, its four major neutralization sites are conformation-dependent, and interaction of GP5 with M is critical for neutralization.⁸ For LDV and PRRSV, the primary neutralization site was mapped close to the GP5 N-terminus and exhibits 77% amino acid identity, probably explaining the observation that LDV neutralizing antibodies to GP5 also neutralize PRRSV.^{154,156} For PRRSV, a second NA-binding domain was identified in the GP4 ectodomain¹²⁹; however, neutralization by monoclonal antibodies directed against this region is less effective than neutralization by GP5 antibodies.²²³ The GP4 region is subject to immune selection, and it is therefore highly heterogeneous among different PRRSV strains.^{40,41}

The production of NA in EAV-infected horses coincides with virus clearance, suggesting that the humoral immune response plays an important role in recovery.⁷⁷ In contrast, NA against LDV and PRRSV are detected only very late, 1 to 2 months after infection, are produced at low levels, and are believed to not or hardly reduce viremia.^{24,58,112,241} One of the most common hypotheses for the delayed or absent NA production in PRRSV infection, or after vaccination, is the presence of an immuno-dominant decoy epitope, just upstream of the GP5 neutralization epitope, which induces a strong nonneutralizing antibody response.¹⁴³ Insertion of another epitope in between the neutralizing and decoy epitopes increased the neutralizing response, suggesting that the juxtapositioning of the two original epitopes indeed plays a role.⁷² In addition, the glycosylation state of the GP5 ectodomain in the vicinity of the neutralizing epitope and glycosylation of GP3 may influence the efficiency of NA production.²²⁰ Similarly, in the case of nonneuropathogenic strains of LDV, the GP5 ectodomain contains three polylactosaminoglycan chains, as opposed to a single polylactosaminoglycan in the ectodomain of neuropathogenic strains. It was postulated that the nonneuropathogenic strains can establish persistent infections because neutralizing antibodies bind less efficiently to the highly glycosylated ectodomain of their GP5. In contrast, neuropathogenic strains are not able to persist.^{32,110,155} Yet another explanation for inefficient neutralization was inspired by the observation that PRRSV infection in piglets manipulates the development of the B-cell repertoire.²¹ Together with the general idea that PRRSV suppresses (innate) immune responses (see below), this may explain the delayed and aberrant antibody production that is observed (reviewed in 43,89,97,114).

The humoral immune response against SHFV varies with the species of monkey and the virus isolate that is tested.^{84,85} The rapid death of macaques after SHFV infection precludes an effective host immune response. Virulent SHFV strains, which cause acute disease in patas monkeys, induced neutralizing antibodies at 7 days postinfection. The production of neutralizing antibodies correlated with the complete clearance of the virus from the circulation by 21 days postinfection.

On the other hand, SHFV strains that cause a persistent infection in these monkeys induce very low antibody titers.

Cell-Mediated Immune Response

Cell-mediated immunity (CMI) to arterivirus infection has not yet been characterized in great detail. Studies in ponies experimentally infected with EAV have shown that cytotoxicity induced by EAV-stimulated peripheral blood mononuclear cells (PBMC) was virus-specific, genetically restricted, mediated by CD8⁺ T cells, and that the precursors persist for at least 1 year after infection.^{5,28}

Cell-mediated responses in PRRSV-infected animals include CD4⁺, CD8⁺, and double positive T cells, which appear transiently between 2 and 8 weeks after experimental infection (reviewed in 43,134,237) or become more pronounced at later stages.¹²⁶ The abundance of PRRSV-specific T cells and IFN- γ -producing cells in both acute and persistently infected animals is highly variable and does not correlate to the level of virus in lymphoid tissue.^{58,126,237} Several studies indicate that the strongest CMI inducers of PRRSV are proteins M, N, and GP4.⁴³

Cytotoxic and helper T-cell responses were detected in LDV-infected mice, but did not reduce LDV replication.⁶⁷ Additional studies are required to determine whether there is a correlation between T-cell responses *in vitro* and protection *in vivo*, and the overall data suggest that the arteriviruses probably directly, or indirectly, manipulate CMI (see below).

Immune Evasion

Not much is known about the mechanistic details of immune evasion by the arteriviruses, but it is clear that modulation of the immune response occurs on different levels. An expanding body of data documents the suppression of innate immune responses (reviewed for PRRSV in 240) and several reports suggest that arteriviruses also manipulate CMI. Downregulation of major histocompatibility complex class I and II (MHC-I and MHC-II) molecules on the surface of antigen-presenting cells (APCs) was shown for PRRSV,^{43,125} and co-infection with LDV causes a delay of the CD8⁺ T-cell-mediated immune response to Friend virus in mice, suggesting manipulation of the MHC-I presentation pathway.¹⁶²

With regard to the molecular mechanisms underlying immune suppressive activities, few data are available at present. Several reports previously suggested that PRRSV significantly induces IL-10 production in pigs during the first 2 weeks of infection. This immunosuppressive cytokine interacts with a wide array of immune cells, including the PRRSV target cells from the monocyte/macrophage lineage, to downregulate in particular cell-mediated innate and adaptive immunity. Recent experiments suggest that PRRSV N may be responsible for IL-10 upregulation during infection, and this may be achieved through induction of specific regulatory T-cell populations.^{172,192,233,240}

In addition to N, three nonstructural proteins have been implicated in arterivirus immune evasion: nsp1 (nsp1 α and nsp1 β in PRRSV), nsp2 (PRRSV and EAV), and nsp11 (PRRSV). All three proteins were suggested to suppress innate immune signaling induced by the RLR- or TLR-innate sensors, or TNF- α , which lead to IFN- β and/or nuclear factor kappa B (NF- κ B) expression.^{16,240} PRRSV nsp1 α and nsp1 β both inhibit the expression of IFN- β after induction of innate responses by Sendai virus or double-stranded DNA (dsRNA),¹⁶ and nsp1 β

also inhibits signaling downstream of type 1 IFNs by inhibiting nuclear translocation of STAT1.³¹ Furthermore, both nsp1 α and nsp1 β suppress NF- κ B activation.^{16,181} Kim et al.⁹⁶ showed degradation of cAMP response element-binding (CREB)-binding protein induced by PRRSV nsp1 during infection, causing inhibition of interferon regulatory transcription factor 3 (IRF3) transcription factor activity in the nucleus. Besides localizing to the perinuclear region with other nsps, nsp1 is partially transported to the nucleus,^{96,197} which may be connected to at least some of its immune evasive activities.

Arterivirus nsp2 contains a papain-like cysteine protease (PLP2) in its N-terminal domain that cleaves the nsp2/nsp3 junction in the replicase polyproteins. This protease is distantly related to the OTU family of deubiquitinating enzymes (DUB).¹²³ Upon overexpression, EAV and PRRSV PLP2 showed a general DUB activity toward cellular ubiquitin conjugates, and also cleaved the IFN-induced ubiquitin homolog ISG15, which is thought to have antiviral activity.⁷⁶ Indications that these DUB activities could be functional in the suppression of innate immune responses were obtained from experiments in which the EAV PLP2-DUB suppressed TNF α -induced NF- κ B signaling in 293T cells. In addition, the PLP2-DUB of PRRSV inhibited the NF- κ B signaling pathway, as well as the IRF3-dependent IFN- β pathway induced by Sendai virus infection.^{109,187} PRRSV PLP2-DUB appears to remove K48-linked polyubiquitin from I κ B α to prevent its proteasomal degradation and thereby downstream signaling toward NF- κ B activation. Besides the PLP2 domain of PRRSV nsp2, also the variable regions in the central part of this large protein could influence antiviral responses.³³ Recent data suggest that PLP2 of all arteriviruses suppresses RLR-mediated IFN- β induction by removing K63-linked polyubiquitin from RIG-I, which results in inhibition of downstream signaling.²¹³

Probably too few data are available at present to firmly establish the suppression of IFN- β production by arterivirus nsp11.¹⁶ The RNase activity of the NendoU domain in PRRSV nsp11 has been implicated in this activity,^{171,240} but it is unclear whether nsp11 confers specific activity targeting certain innate immune responses or might attack the overall mRNA population of the cell on the basis of its RNase activity, thus inducing a translational shut-off.

RELEASE FROM THE HOST AND TRANSMISSION

In nature, EAV and PRRSV are transmitted primarily via the respiratory route.^{199,226} Both viruses may persist in the semen of infected male animals, and are shed in milk of infected female animals, making vertical transmission an important secondary route of infection. In addition, LDV is efficiently transmitted from mother to fetus,²⁵⁰ and also sexual transmission was reported.²³ PRRSV was shown to replicate in testicular germ cells such as spermatids and spermatocytes¹⁸⁸; infectious EAV is excreted in semen by persistently infected “carrier” stallions and can be transmitted to broodmares.^{5,199} Both EAV and PRRSV are furthermore shed in virtually all body secretions, including saliva, respiratory tract secretions, oropharyngeal secretions, urine, and feces (reviewed in 38,88). PRRSV can also be mechanically transmitted in pig herds through aerosols, infected needles, contaminated boots and coveralls, and carrier insects like

houseflies.^{38,144,151} In contrast to the other arteriviruses, SHFV is not transmitted transplacentally from mother to offspring.⁸⁵

VIRULENCE

Sequence comparisons revealed that the highly pathogenic PRRSV strain causing the “porcine high fever disease” in Asia since 2006 originated from Chinese domestic type II viruses (which are related to the VR-2332 genotype II prototype strain).²³⁶ They all have the same striking deletions of a conserved leucine and a 29-amino acid stretch in *nsp2*,^{107,170,194} but these typical differences were found to be unrelated to the increased virulence.²⁴⁷

Infectious full-length cDNA clones were constructed of both cell culture-adapted²⁰⁸ and virulent⁷ EAV isolates, which can be used to study the determinants of virulence. Comparative sequence analysis of EAV strains that differ in virulence identified potentially relevant amino acid substitutions in both structural and nonstructural proteins. Reverse genetics experiments then showed that substitutions in the structural proteins may lead to more severe attenuation than those in the nonstructural proteins.²⁴⁴ Collectively, interactions of both major (GP5 and M) and minor (GP2, GP3, and GP4) envelope proteins seem to influence tropism, and mutations in these proteins can therefore affect virulence.⁸⁰

PERSISTENCE

Typical for natural EAV infections is the persistence that occurs in about 35% of the infected stallions.¹⁹⁹ The virus persists in the reproductive tract of these “carrier stallions” and is continuously shed into the semen for a long time. In contrast, persistent infection in mares generally does not last longer than one month.⁸⁸ The establishment and maintenance of persistent infection is testosterone-dependent in stallions, and high serum titers of neutralizing antibodies are insufficient to clear the virus.^{5,199} A study of EAV evolution in persistently infected stallions strongly suggested that neither defective interfering particles nor immune evasion from B-cell responses are involved in persistence.⁹

Persistence of PRRSV has been commonly observed for up to 150 days in pigs, and up to 210 days in congenitally infected piglets.³⁵ Although the mechanisms underlying the failure to promptly clear PRRSV infection are poorly understood, it appears that a major reason is the inability of pigs to develop effective protective immune responses, which is probably due to the concerted immune evasion strategies exploited by the virus.^{117,125}

SHFV appears to be endemic among several species of African monkeys, in which it causes asymptomatic acute or persistent infections depending on the virus strain.¹¹³ LDV is also able to establish a largely asymptomatic persistent infection.¹⁵⁵

EPIDEMIOLOGY

EAV

Despite its worldwide distribution, EAV has not caused many disease outbreaks. The first recognized and most severe epizootic occurred in 1953 in Bucyrus, Ohio, U.S.A.⁶² Milder out-

breaks have been reported from elsewhere in the United States, Canada, and a variety of European countries, with recent epizootics occurring in Normandy (France, 2006) and New Mexico (U.S.A., 2007).⁸⁸ The apparent discrepancy between the high incidence of the virus and the relatively low number of recorded disease outbreaks is explained by the predominantly subclinical course of infection.

A recent genome-wide association study pin-pointed genetic differences within and among horse populations that are associated with susceptibility of CD3+ T lymphocytes to EAV infection *in vitro*.⁷⁸ The genomic region identified encodes proteins (potentially) involved in virus entry, cytoskeletal organization, and antiviral innate responses, and the association of a specific haplotype (ECA11) with susceptibility to EAV infection will allow the development of a targeted molecular test for diagnostic purposes and large-scale studies.

PRRSV

PRRS was first detected in 1987 in the United States,³⁶ and the first outbreaks in Europe were recognized in Germany in 1990.^{225,227} Today, PRRSV infection is ubiquitous in all swine-producing areas of the world, including North and South America, Europe, and Asia. Severe abortion storms had a resurgence in 1996 to 1998 in the United States. Subsequently, the number of acute disease outbreaks decreased until atypical PRRSV variants emerged in China in 2006, causing outbreaks of fatal PRRSV that were unparalleled in severity. The novel variant usually spread through a herd within 3 to 5 days, causing morbidity between 50% and 100%. Mortality rates in the 2006 outbreak were high, with a mean around 20%, and they could be as high as 100% in suckling piglets, 70% in nursery pigs, and 20% in finishing pigs. More than 40% of pregnant sows suffered abortion and 10% of these sows themselves succumbed to the disease.^{111,194,246} In the following years, this highly pathogenic PRRSV spread to all Chinese swine-producing areas as well as surrounding Asian countries. About 60% of the Chinese pigs were infected with PRRSV over the 5 years after the virulent virus emerged.¹⁰⁷ To improve infection control, porcine genetic markers associated with PRRSV susceptibility are being sought, which can be used in breeding programs to optimize virus resistance, in balance with other traits of economic importance in pig production such as feeding efficiency, meat production, and leanness (reviewed in 116).

LDV

LDV was first discovered in laboratory mice.^{155,161} The virus was also isolated from wild mice in several countries, although the worldwide incidence is not known. Despite a life-long viremia and virus secretion in urine, feces, and saliva, horizontal transmission is inefficient, except in the case of fighting males. In contrast, transmission from mother to offspring is much more efficient, as long as anti-LDV immune responses have not yet been elicited.¹⁵⁵

SHFV

SHFV appears to be endemic among several species of African monkeys (*Erythrocebus patas*, *Ceropithecus aethiops*, *Papio anubus*, and *Papio cyanocephalus*).^{85,103,113} Nevertheless, the virus was first isolated from Asian macaques, during outbreaks of fatal hemorrhagic fever in research centers in the Soviet Union and the United States.¹⁸⁹ These epizootics were probably

caused by inadvertent transmission by humans from African monkeys to the macaques. During these outbreaks, SHFV was readily transmitted from the initially infected rhesus monkeys (*Macaca mulatta*) to other macaque species (*Macaca fascicularis* and *Macaca arctoides*), most likely by direct contact and via aerosols, whereas members of other monkey genera did not show clinical symptoms. Subsequently, similar epizootics among macaques occurred in various other primate centers.

CLINICAL FEATURES

EAV

The manifestations of EAV infection after an incubation period of 2 to 14 days range from subclinical to flu-like symptoms in adult animals, abortion in pregnant mares (e-Fig. 29.10A), persistent infection in stallions, and interstitial pneumonia in neonates.^{5,62,88} As with most infectious diseases, old, debilitated, or immunosuppressed horses and very young foals are predisposed to more severe disease.⁸⁸ Clinical features are characteristic vascular lesions, necrosis of small muscular arteries (from which the name of the family prototype EAV was derived), acute anorexia, and fever, usually accompanied by palpebral edema, conjunctivitis, nasal catarrh, and edema of legs, genitals, and abdomen (62, e-Fig. 29.10). Virulence and clinical signs are strain dependent, but the genetic basis for these differences has not been established.¹⁹⁹

PRRSV

At 12 to 24 hours after exposure to PRRSV, young pigs, sows, and boars become viremic, a state that can last from 1 to 2 weeks in mature animals to 8 weeks in young pigs. Clinical manifestations of PRRSV include occasional discoloring and blotching of the skin, most often on the ears (which gave PRRS the name “blue ear disease”) and vulva, and occasionally on the trunk. Further symptoms are fever, anorexia, breathing difficulties, lymphadenopathy, gross and microscopic lesions in the lung, and reproductive failure characterized by delivery of weak or stillborn piglets (e-Fig. 29.11A), or autolyzed fetuses.²²⁵

The clinical features of the highly pathogenic PRRSV variants that emerged in China in 2006 are strikingly more severe than those reported for the older isolates (e-Fig. 29.12). The new variant affected pigs of all ages and was characterized by high fever (40 to 42°C), depression, anorexia, lethargy, and rubefaction of the skin and ears. Most diseased pigs showed obvious respiratory distress, such as sneezing, coughing, and asthma, as well as intestinal problems including diarrhea. At autopsy, the severe lesions in skin, lung, gastrointestinal tract, and brain were considered unique for this atypical form of PRRS^{194,246} (e-Fig. 29.12F). Mortality rates ranged from 20% to 100%, depending on the age and health of the infected animals.

LDV

Infection of mice with LDV leads to a life-long viremia, but the infection is asymptomatic. It is maintained by continuous rounds of cytocidal virus replication in a renewable subpopulation of macrophages.¹⁴² By 24 h after infection, LDV titers of 10^{10} infectious dose (ID)₅₀/ml are present in the plasma, which then decrease to a level of 10^4 to 10^6 ID₅₀/ml. These titers remain present throughout the life of the mouse, together with elevated levels of lactate dehydrogenase and

other serum enzymes, which is due to the destruction of the macrophages that play a role in their clearance. LDV can be detected in the spleen, lymph nodes, thymus, and liver of persistently infected mice. Neurovirulent LDV variants can cause a fatal age-dependent poliomyelitis in certain inbred mouse strains that are of the Fv-1^{n/n} genotype and carry N-tropic, ecotropic murine leukemia virus (MuLV) proviruses³⁷ (e-Fig. 29.13). The replication of these ecotropic MuLVs in the glial cells of the spinal cord was proposed to render the anterior horn neurons susceptible to cytocidal LDV infection. Consequently, the development of age-dependent poliomyelitis may result from a combination of increased expression of ecotropic MuLVs and a decreasing ability to mount a motor neuron-protective anti-LDV response. LDV can also induce severe thrombocytopenia in animals that have been treated with anti-platelet antibodies at a dose that in itself was insufficient to induce clinical disease.^{135,136} The mechanism is unknown, but macrophage activation by virus-induced IFN- γ production is likely to play an important role.

SHFV

Depending on the virus strain, SHFV causes asymptomatic acute or persistent infections in several species of African monkeys,^{85,113} whereas in captive macaques fatal hemorrhagic fever was reported upon SHFV infection¹⁸⁹ (e-Fig. 29.14). Clinical signs in the latter animals consist of early fever, mild facial erythema, and edema, followed by anorexia, dehydration, and various hemorrhagic manifestations. The macaques usually die within 2 weeks, with mortality rates approaching 100%. Very little is known about SHFV pathogenesis in macaques. Macrophages are the primary target cells for SHFV, and a causal relationship exists between the cytocidal infection of these cells and the clinical symptoms of hemorrhagic fever.⁸⁴

PREVENTION AND CONTROL

Diagnosis

Diagnosis of EAV or PRRSV infections on the basis of clinical signs alone is generally very difficult, and therefore not reliable. This is due to the often subclinical or mild symptoms that resemble the symptoms of other respiratory diseases of horses and swine. Differential diagnosis of EAV- or PRRSV-induced abortions are also not straightforward, although these are generally characterized by (partial) autolysis of the fetuses and a lack of pathognomonic lesions, which is for example different for equine herpesvirus-induced abortions where aborted fetuses are usually fresh.⁸⁸

For laboratory diagnosis of EAV, nasopharyngeal swabs or washings, conjunctival swabs, and blood samples can be used. Several reverse transcriptase polymerase chain reaction (RT-PCR) assays are available for detection of EAV RNA in such clinical samples. In addition, immunohistochemistry using monoclonal antibodies to EAV proteins is a reliable method for EAV diagnosis in tissues. A virus neutralization assay remains the gold standard for detection of serum antibodies against EAV.⁸⁸

PRRSV infection can be diagnosed from pig serum or semen samples from boars, umbilical cords from piglets at birth, or serum samples from weaned sows, using fluorescence microscopy, enzyme-linked immunosorbent assay (ELISA), or an RT-PCR test. Recent studies established that PRRSV detection in

oral fluids of boars is an alternative to serum and semen sampling, since it gave very similar results, but with far less invasive sampling procedures. These oral samples were collected from cotton ropes impregnated with apple juice and sugar, which the animals were allowed to chew for approximately 20 minutes. Subsequently, fluids were mechanically extracted from the wet ropes and used to measure the presence of PRRSV RNA^{98,102} or PRRSV-specific antibodies.^{102a}

Disease Control

Equine viral arteritis is a manageable disease. Effective strategies for prevention and control have been designed, and uniform methods and rules have been published by the U.S. Department of Agriculture–Animal and Plant Health Detection Service (USDA-APHIS). These include directions to prevent spread of the virus in horse breeding populations, which usually suffice to suppress the further spread of infection.

Since 2006, the outbreaks of highly virulent PRRSV variants in Asia have boosted research aimed at the development of efficient control strategies against all variants of this virus, which continues to cause significant economic losses worldwide. Changes in swine management have been proven effective in preventing PRRSV outbreaks and are presently thought to be key to controlling the disease in the less intensive swine industry. The method of herd closure, for example, involves the uniform exposure of a confined herd to PRRSV, followed by a continued isolation of the herd for more than 200 days. This effectively eliminates PRRSV, as long as no new animals, and thereby possibly new PRRSV strains, are introduced from outside. In addition, strict biosecurity protocols, including air filtration, have been shown effective (reviewed in 38,46,133 and references therein). In areas with highly intensive pig farming this type of relatively costly strategies are often difficult to implement, and the need for better PRRSV vaccines than those currently available is high (see below).

Because arteriviruses generally infect production or laboratory animals, low priority has been given to the development of antiviral treatments. Infected animals either die quickly of the disease, or are culled as a way to prevent further spread.

Vaccines

For EAV, several genetically engineered candidate vaccines have been developed and tested in experimental infections. Some promising results were obtained with a vaccine based on Venezuelan equine encephalitis virus replicon particles expressing both EAV GP5 and M. Horses vaccinated with this recombinant vaccine produced neutralizing antibodies, shed little or no virus, and developed only mild symptoms after a challenge with virulent EAV.⁴ An EAV candidate live marker vaccine was developed on the basis of the deletion of the immunodominant domain of GP5, for which a peptide-specific ELISA is available.²⁹ This recombinant virus caused an asymptomatic infection in ponies and induced neutralizing antibodies, albeit only against the recombinant and not against the wild-type virus. The vaccinated animals were fully protected against disease following a challenge with virulent EAV.²⁹ The ELISA for the deleted immunodominant domain can be used to distinguish between vaccinated and naturally infected animals.

For PRRSV, a variety of live-attenuated and killed vaccines are commercially available. The MLV vaccines induce

long-lasting protection, but when derived from a single PRRSV vaccine strain they do not fully protect against heterologous PRRSV infection.⁹⁷ Furthermore, MLV vaccines do not completely prevent reinfection with wild-type virus and virus transmission. In some situations, it is impossible to discriminate between vaccinated and naturally infected animals. Either a subunit vaccine or a genetically modified live marker vaccine could overcome this problem, although the use of recombinant viruses in the field continues to be debated between vaccine developers, swine practitioners, and animal health authorities.

Adverse effects of vaccination of Danish pig herds with a modified live PRRS vaccine have been described, which were probably caused by reversion of the vaccine virus to virulence. Acute PRRS-like symptoms, including an increasing number of abortions and stillborn piglets, were experienced in vaccinated herds. Furthermore, vaccine virus was transmitted from vaccinated to nonvaccinated boars in several cases, resulting in viremia and shedding of vaccine virus in the semen.^{17,89,120,183} In addition, in Thai swine farms, vaccine-derived viruses were found to spread² and homologous recombination with circulating virus was observed in China.¹⁰⁸ In this respect, the killed vaccines are safer but they are less efficacious in the induction of protection.^{217,252} In general, it is believed that the strong immunomodulatory capabilities of PRRSV prevent the mounting of an efficient vaccine-induced immune response, and that the limited level of immunity that can be induced is insufficient to protect against challenging viruses.^{89,192}

Some promising results were obtained in DNA vaccination experiments with plasmids expressing PRRSV GP5.^{10,97,150} Neutralizing antibodies and lymphocyte proliferation were detected in DNA-vaccinated pigs, and the spread and clinical signs of challenge virus were reduced. This DNA immunization protocol was, however, not sufficient to prevent virus persistence and shedding in the respiratory tract. Combination with plasmids encoding M or GP3 in some cases increased the immune efficacy of candidate PRRSV DNA vaccines, as did co-delivery with plasmids encoding IFN- γ and IL-2.^{92,93,163,239} These results suggest that PRRSV GP5 may at least be a basis for a DNA-based subunit vaccine. Protection against clinical disease and reduction of pathogenic lesions were also observed with a recombinant pseudorabies virus vaccine expressing PRRSV GP5¹⁵⁹ and a recombinant transmissible gastroenteritis coronavirus expressing GP5 and M.⁴² Nevertheless, the genetic instability of heterologous genes inserted in these vaccine vectors remains to be solved. Using reverse genetic systems, chimeric infectious cDNA clones have been engineered aimed at developing attenuated modified live virus (marker) vaccines. Chimeric infectious clones in which sequences from virulent field strains were combined with attenuated vaccine strains gave some promising results.²²¹ The possibility to engineer marker vaccines was demonstrated by the removal of one or multiple conserved immunodominant B-cell epitopes from PRRSV nsp2, which resulted in viable marker viruses eliciting useful immune responses.⁴⁹ These deletions themselves, however, did not attenuate the virus, unless a green fluorescent protein marker gene was inserted at the site of the deletion. In this manner, an attenuated virus with both a negative and a positive marker was engineered, although the foreign insert proved to be genetically instable.⁷³

A novel approach to increase the immunogenicity of viral subunits is to facilitate their uptake into dendritic cells

(DCs) by inducing the expression of appropriate surface receptors (reviewed in 89). Proof of principle for this approach was recently obtained for CD169, one of the surface receptors for PRRSV, using anti-CD169 monoclonal antibodies as test ligands, which indeed induced *in vitro* T-cell proliferation at 100-fold lower concentrations than the nontargeting control ligand.¹⁶⁰ When more data will become available about the induction of regulatory T cells by PRRSV, this knowledge could be applied to improve vaccine efficacy as well. Removal of viral activities that suppresses innate immune responses is a strategy that is being developed for other viruses like influenza virus, where the innate immune “evasion” NS1 can be removed to produce a viable, attenuated vaccine virus. However, for arteriviruses, this may be far more difficult, since the viral proteins presently thought to suppress innate immunity are indispensable for virus viability.⁸⁹

PERSPECTIVES

A variety of important issues remain to be addressed in future studies of arteriviruses. Most of the viral proteins have been defined in basic terms only, and understanding the molecular details of their role in the viral life cycle is one of the major challenges for arterivirus research. For example, the characterization of the now eight structural proteins and their functional interactions during particle assembly and disassembly promises to be a highly complex issue, which also links to the many unanswered questions regarding host cell functions relevant for arterivirus attachment and entry.

In recent years, prompted in particular by the enormous PRRSV problems in Asia, determinants of arterivirus pathogenesis and virulence have received a lot of attention. The outline of a highly complex interplay between arterivirus and host is emerging, which will undoubtedly prove to be a critical factor in future vaccine development as well. Reverse genetics will continue to be a crucial tool for both basic and applied research in this area.

Our understanding of arterivirus epidemiology and evolution must be improved to prevent problems like the Asian PRRS outbreak in the future, and this field also connects to the interesting question of the potential for arterivirus cross-species transmission. On a different evolutionary level, that of the order *Nidovirales*, arteriviruses continue to be part of a unique group of positive-strand RNA viruses that is characterized by having the largest and most complicated replication machinery among currently known RNA viruses. In anticipation of systems allowing the complete *in vitro* reconstitution of arterivirus RNA synthesis, progress will continue to depend on successfully combining bioinformatics, biochemistry, and structural and molecular biology. This powerful approach has already provided detailed insights in some of the intricacies of arterivirus RNA synthesis, replication structures, and virus–host interactions, which will also be key to the design of antiviral strategies to combat diseases caused by known or currently unknown arteriviruses. Modern virus hunting techniques are increasingly likely to identify such additional family members in the years to come. This might compensate for the fact that—based on the inapparent and persistent infections frequently caused by currently known arteriviruses—clinical symptoms may not be the most direct indicator for arterivirus infections in other species.

Mononegavirales

Host Range
Morphology
Lipids
Proteins
Nucleic Acid, Genome Organization, and Replication

The Eighth Report of the International Committee on the Taxonomy of Viruses (ICTV) (2005)¹ has recognized a hierarchy of viral taxa as follows: (order), family, (subfamily), genus, and species. Only three recognized orders of viruses are listed: *Caudovirales*, *Nidovirales*, and *Mononegavirales*. To avoid duplication of literature citations with the chapters on *Paramyxoviridae* (Chapter 33), *Rhabdoviridae* (Chapter 31), *Filoviridae* (Chapter 32), and *Bornaviridae* (Chapter 39) only the minimal list of references

that are unique to this chapter are cited. For full documentation of facts discussed here, see the specific chapters describing each family of the *Mononegavirales*. Table 30.1 lists nomenclature derivations relevant to this material.

The order *Mononegavirales* is composed of four families that have a phylogenetic relationship. Examples of the members of the *Mononegavirales* are shown in Table 30.2. These enveloped viruses possess linear, nonsegmented, negative-sense, single-stranded RNA (ssRNA) genomes. The four families are *Paramyxoviridae*, *Rhabdoviridae*, *Filoviridae*, and *Bornaviridae*. The common features of three families—*Paramyxoviridae*, *Rhabdoviridae*, and *Filoviridae*—include the negative strand-ness of the monopartite RNA genome; a similar gene order (3'-untranslated region [UTR]-core protein genes-envelope protein genes—a large polymerase gene—5' UTR) (Table 30.3);

TABLE 30.1 Nomenclature Derivations

Borna	From Borna, a town in Saxony, Germany
Cyto	From Greek, <i>kytos</i> , "cell"
Ebola	From the river Ebola, Zaire
Ephemer	From Greek, <i>ephemeros</i> , "ephemeral"
Filo	From Latin, <i>filo</i> , "thread-like"
Lyssa	From Greek, <i>lyssa</i> , "rage, fury, canine madness"
Marburg	From the city of Marburg, Germany
Meta	From Greek, <i>meta</i> , "after"
Mono	From Greek, <i>monos</i> , "single"
Morbilli	From Latin <i>morbillus</i> , diminutive of <i>morbus</i> , "disease"
Nega	Modern invention from negative-sense RNA
Novi	Modern invention (no- and vi-) to describe a characteristic of the genus
Nucleo	From Latin <i>nux</i> , "nut"
Paramyxo	From Greek <i>para</i> , "by the side of," and <i>myxo</i> , "mucus"
Pneumo	From Greek, <i>pneuma</i> , "breathe"
Respiro	From Latin, <i>respirare</i> , "to breathe"
Rhabdo	From Latin, <i>rhabdos</i> , "rod"
Rubula	From Latin, <i>rubber</i> , "red"; <i>rubula inflans</i> was the old name for mumps.
Vesiculo	From Latin, <i>vesicula</i> , diminutive of <i>vesica</i> , "blister"
Virales	From Latin, "viruses"

TABLE 30.2 Taxonomic Structure of the Order *Mononegavirales*

Order	<i>Mononegavirales</i>
Family	<i>Bornaviridae</i>
Genus	<i>Bornavirus</i>

Genes encoding proteins of presumed homologous function are aligned vertically.

Virus abbreviations: ARV, Adelaide River virus; BDV, borna disease virus; BEFV, bovine ephemeral virus; HeV, Hendra virus; HRSV, human respiratory syncytial virus; IHNV, infectious hematopoietic necrosis virus; MARV, Lake Victoria Marburgvirus; MeV, measles virus; MuV, mumps virus; RV, rabies virus; SeV, Sendai virus; SYNV, Sonchus yellow net virus; TRTV, turkey rhinotrachitis virus; VSV, vesicular stomatitis virus; ZEBOV, Zaire ebolavirus.

Gene order abbreviations: Le, noncoding leader region; NS, nonstructural protein gene; N, nucleocapsid protein, P, phosphoprotein/N protein chaperone; V protein, interferon antagonist in most cases; C protein, interferon antagonist and involved in virus assembly; Sc4 and 4b, genes of unknown function, M and M1, matrix protein gene; F, fusion protein gene; SH, small integral membrane protein that may block apoptosis; G (or H or HN), attachment protein (hemagglutinin or hemagglutinin-neuraminidase; SP, secreted version of G; M2 envelope protein gene, Ps, pseudogene; NV, nonvirion protein gene; Gns, presumptive duplicated G sequence; L, large (polymerase) protein; tr, noncoding trailer region.

helical nucleocapsids; initiation of transcription by the virion-associated, RNA-dependent RNA polymerase (RdRp) from a single 3'-promoter; utilization of a stop-start transcription mechanism for each cistron; complementarity of the genome at the immediate 3' and 5' ends (to act as polymerase promoters); and 93% to 99% of the genome is protein encoding. The ribonucleoprotein (RNP) cores are infectious, but naked RNA is not infectious because it is not in the form of an RNP with its associated RdRp. Maturation is by budding from a cellular membrane and most members of the *Mononegavirales* bud from the plasma membrane, although rabies virus can bud into intracellular membranes and some plant rhabdoviruses are thought to bud from the inner nuclear membrane.

The family *Bornaviridae* has a unique pattern of messenger RNA (mRNA) processing among the *Mononegavirales*

as it utilizes the cellular splicing machinery to process precursor RNA to mRNA. The family *Bornaviridae* is included in the order *Mononegavirales* based on the negative strandedness of the monopartite genome ssRNA, similarity of the order of related genes, complementarity of the immediate 3' and 5' ends of the genome, and the relatedness of the transcription start and stop signals. Bornaviruses, however, are different from the other three families because their replication and transcription occurs in the nucleus, whereas replication of the families *Paramyxoviridae*, *Rhabdoviridae*, and *Filoviridae* (with the exception of plant viruses in the genus *Nucleorhabdovirus*) occurs in the cytoplasm. The phylogenetic relationship among the families *Paramyxoviridae*, *Rhabdoviridae*, *Filoviridae*, and *Bornaviridae* are illustrated in Figure 30.1. The phylogenetic relationship among members of the family *Paramyxoviridae* is shown in greater detail in Figure 30.2.

FIGURE 30.1. Unrooted phylogenetic tree of members of the order *Mononegavirales*. The tree was constructed using the CLUSTALX program with the sequences of the conserved domain III of the polymerase proteins. Three paramyxoviruses formerly unclassified by the International Committee on the Classification of Viruses (ICTV) are included: Tupaia paramyxovirus (Tupaia), avian parainfluenza virus type 6 (APaV6), and Tioman virus (Tioman). BDV—, Borna disease virus; BEFV—, bovine ephemeral fever virus; CDV—, canine distemper virus; HeV—, Hendra virus; HMPV—, human metapneumovirus; HRSV—, human respiratory syncytial virus; MARV—, Marburg virus; MeV—, measles virus; MuV—, mumps virus; NDV—, Newcastle disease virus; NiV—, Nipah virus; PIV3—, parainfluenza virus type 3; PVM—, pneumonia virus of mice; RABV—, rabies virus; SeV—, Sendai virus; PIV5—, parainfluenza virus 5, formerly known as simian virus 5 (SV5); TRTV—, turkey rhinotracheitis virus; VSV—, vesicular stomatitis Indiana virus; ZEBOV—, Zaire Ebola virus. (From Fauquet CM, Mayo MA, Maniloff J, et al., eds. *Virus Taxonomy. Eighth Report of the International Committee on the Taxonomy of Viruses*. London: Elsevier/Academic Press; 2005, with permission.)

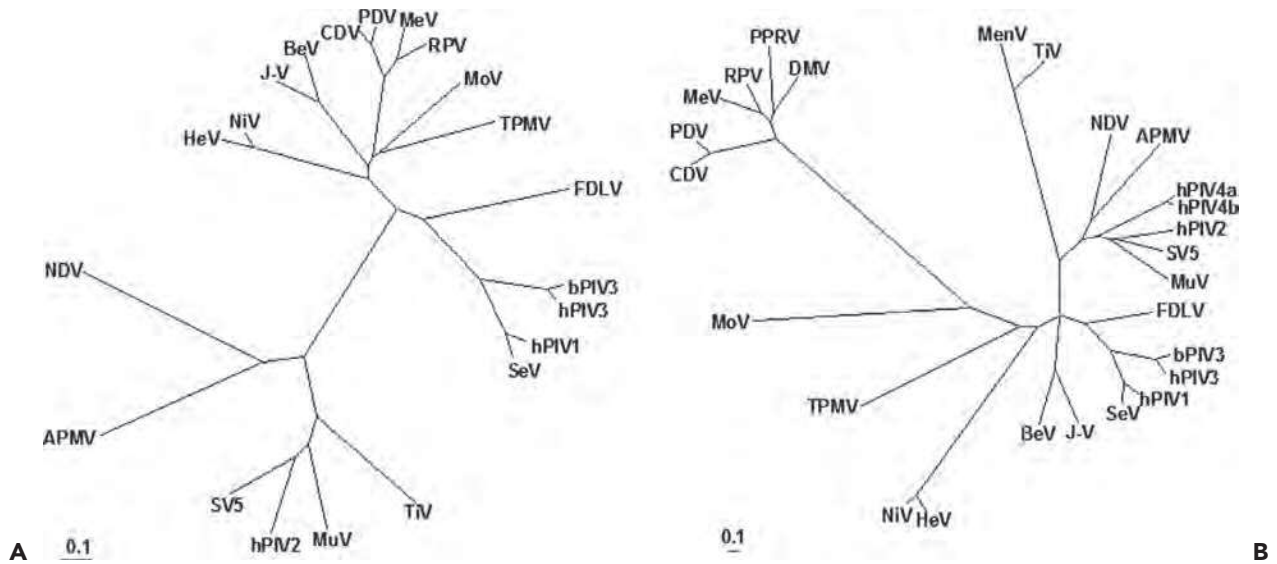

FIGURE 30.2. Unrooted phylogenetic trees based on complete L protein (A) and attachment protein (B) sequences of selected viruses within the subfamily *Paramyxovirinae*. The trees were generated from ClustalW (accurate) protein alignments using distance matrix programs (Protdist and Neighbor) within the PHYLIP software package and drawn in TreeView. Branch lengths represent relative genetic distances. GenBank accession number sequences used to generate the phylogenetic tree are listed below. For viruses in which a full-length genome sequence was not available, individual gene sequences were used and are indicated by the abbreviated gene letter in parentheses followed by the accession number. Avian paramyxovirus type 6 (APMV6) AY029299; BeV DQ100461; bovine parainfluenza virus 3 (bPIV3) AF178654; bovine respiratory syncytial virus (bRSV) AF092942; canine distemper virus (CDV) AF014953; Cetacean morbillivirus (CMV) strain Dolphin morbillivirus (DMV) X75961(N), Z47758(P/V/C), Z30087(M), Z30086(F), Z36978(H); Fer-de-Lance virus (FDLV) AY141760; Hendra virus (HeV) AF017149; human parainfluenza virus 1 (hPIV1) AF457102; human parainfluenza virus 2 (hPIV2) X57559; human parainfluenza virus 3 (hPIV3) AB012132; human parainfluenza virus 4a (hPIV4a) M32982(N), M55975(P/V), D10241(M), D49821(F), M34033(HN); human parainfluenza virus 4b (hPIV4b) M32983(N), M55976 (P/V) D10242(M), D49822(F), AB006958(HN); human respiratory syncytial virus (hRSV) AF013254; J virus (J-V), AY900001; measles virus (MeV) AB016162; Menangle virus (MenV) AF326114 (N,P/V,M,F,HN); Mossman virus (MoV) AY286409; mumps virus (MuV) AB040874; Newcastle disease virus (NDV) strain Beaudette C AF064091(N), X60599(P/V), X04687(M), X04719(F), X04355(HN), X05399(L); Nipah virus (NiV) AF212302; Peste-des-petits-ruminants virus (PPRV) X74443(N), AJ298897(P/V/C), Z47977(M), Z37017(F), Z81358(H); Phocine distemper virus (PDV) X75717(N), D10371(P/V/C, M, F, H), Y09630(L); Rinderpest virus (RPV) Z30697; Sendai virus (SeV) AB005795; simian virus 5 (SV5) AF052755; Tioman virus (TiV) AF298895; Tupaia paramyxovirus (TPMV) AF079780. (Adapted from Li Z, Yu M, Zhang H, et al. Beilong virus, a novel paramyxovirus with the largest genome of non-segmented negative-stranded RNA viruses. *Virology* 2006;346:219–228.) PHYLIP software package available from Joseph Felsenstein, Department of Genome Sciences, University of Washington, Seattle, Washington.

HOST RANGE

The host range of *Mononegavirales* varies from restricted to unrestricted. Filoviruses have been isolated from primates only. Paramyxoviruses are found only in vertebrates and there are no known vectors. In contrast, rhabdoviruses infect invertebrates, vertebrates, and plants. Some rhabdoviruses multiply in both invertebrates and vertebrates, some in invertebrates and plants, but no known example exists of a rhabdovirus that replicates in vertebrates and plants. In humans the families *Paramyxoviridae*, *Rhabdoviridae*, and *Filoviridae* can cause mild to severe morbidity and mortality, for example: hemorrhagic fever (Ebola and Marburg), neurologic disease (rabies virus), respiratory and neurologic disease (paramyxoviruses: measles virus, mumps virus, parainfluenza viruses 1 to 4, Nipah virus and Hendra virus, respiratory syncytial disease virus, and human metapneumovirus). The paramyxoviruses—parainfluenza virus 5, Newcastle disease virus, canine distemper virus, phocine distemper virus, Nipah virus, Hendra virus, pneumonia-like virus of mice, turkey rhinotrachitis virus and the rhabdoviruses,

vesicular stomatitis virus, and rabies virus—cause disease in animals. Bornaviruses have been isolated from horses, cattle, sheep, rabbits, rats, cats, and humans. Infection of some model animals is associated with behavioral disturbances to severe nonpurulent encephalomyelitis. There has been great debate concerning whether bornaviruses can cause psychological disease in humans.

MORPHOLOGY

The defining characteristic of all members of *Mononegavirales*, except the family *Bornaviridae*, is that the virions are large, enveloped structures containing a visible fringe of spike glycoproteins. The families exhibit very different shapes, however. Members of the family *Paramyxoviridae* are filamentous or pleomorphic (somewhat) spherical particles (200 to 300 nm in diameter), whereas members of the family *Filoviridae* are bacilliform, forming long threads (800 nm). Viruses within the family *Rhabdoviridae* are regular bullet-shaped particles or

bacilliform. The viral nucleocapsid (ribonucleoprotein [RNP]) is often observed in ruptured virion particles on an electron microscopy (EM) grid and the nucleocapsids have a diameter of 13 to 20 nm and characteristic morphologies, depending on the particular virus family.

LIPIDS

The lipid composition of the *Mononegavirales* reflects that of the host cell membrane from where the virions bud. Some of the spike glycoproteins have fatty acid covalently linked to their cytoplasmic tails.

PROTEINS

Members of the *Mononegavirales* contain five to seven structural proteins: the envelope glycoproteins; a matrix protein that underlies the lipid envelope; a major RNA binding protein often called the nucleocapsid protein (N or NP); other nucleocapsid-associated proteins; and a very large protein that has RdRp activity and capping, methylating, and polyadenylate transferase activities. The viruses also encode several nonstructural proteins, several of which are involved in antagonizing the innate immune system. Some viruses have a single glycoprotein that mediates both attachment of the virion to the cellular receptor and fusion of the viral envelope to a cellular membrane for viral entry into the cell. Other viruses have two major spike glycoproteins, one of which has attachment activity and the other of which has membrane fusion activity. When the receptor is sialic acid, the attachment protein usually has a neuraminidase activity that acts as a receptor-destroying activity.

NUCLEIC ACID, GENOME ORGANIZATION, AND REPLICATION

Members of the *Mononegavirales* contain one molecule of negative-sense ssRNA that varies from 8.9 to 19 kilobases (kb). The RNA is not infectious; by definition, a negative-sense RNA has to be copied to a plus-sense RNA to be translated to protein and the naked RNA of the *Mononegavirales* has to be packed into an RNP with its associated RdRp. The 5' end of the genome RNA is not modified by a cap structure or addition

of a covalently linked protein and the 3' end of the genome RNA is not polyadenylated. The immediate 5'- and 3'-termini exhibit inverse complementarity and are used as promoters by the RdRp for synthesis of both the antigenomic full-length positive RNA strand and the new genome RNA. The genome is composed of a series of genes with limited overlaps in some viruses (e.g., respiratory syncytial virus). The RdRp transcribes the genes in sequential order from the 3' end of the genome to make a series of mostly monocistronic mRNA. Transcription is polar with step-wise attenuation. Examples of the use of overlapping translational reading frames are found. Mostly, the genes have short 5' and 3' UTR (notable exceptions are found for Nipah virus, Hendra virus, J virus, and Beilong virus² of the paramyxovirus family). Conserved nucleotide sequence motifs define the transcriptional gene start with addition of a cap structure to the mRNA and conserved nucleotide sequence motifs that define the gene end and cause the addition of poly(A) to the mRNA in all families. A region of genome RNA between the gene-end and gene-start sequences is found, which is called the intercistronic region. This region is not transcribed into mRNA and can range from two nucleotides to hundreds of nucleotides. Members of the subfamily *Paramyxovirinae* undergo an insertion of nontemplated nucleotides at a pseudo-poly(A) addition site within their "P" gene to give rise to additional mRNA encoding extra proteins. A related event occurs in the glycoprotein gene of Ebola virus, giving rise to two versions of the glycoprotein. Splicing of mRNA only occurs for bornaviruses. In the subfamily *Paramyxovirinae* of the family *Paramyxoviridae*, the genome length in nucleotides has to be a number divisible by six (the so-called "rule of six"). It is thought that this constraint is because each nucleocapsid protein subunit binds to precisely six nucleotides to form the RNP.

Perspectives

The family *Rhabdoviridae* consists of more than 185 different viruses isolated from both plants and animals. They are enveloped viruses that have helical nucleocapsids containing single-stranded, negative-sense RNA and share a common elongated, rod-like or bullet-like shape. This distinctive morphology separates rhabdoviruses from other taxa in the order *Mononegavirales*, the *Bornaviridae*, the *Filoviridae*, and the *Paramyxoviridae*. Rhabdoviruses can replicate in plants, invertebrates, or vertebrates. The family *Rhabdoviridae* contains many members that are significant medical, veterinary, and agricultural pathogens. Currently, animal rhabdoviruses include four genera: *Lyssavirus*, *Vesiculovirus*, *Ephemerovirus*, and *Novirhabdovirus* (Table 31.1). Many other rhabdoviruses have not received adequate study and are assigned to the family solely on the basis of morphology.

HISTORY

Lyssaviruses

Rabies is an archaic entity, one of the oldest recognized infectious diseases. The continuing biomedical preoccupation with rabies is understandable because of its “alarming manifestations in man and dog alike . . . and its almost inevitable progression to a fatal outcome have ensured unparalleled notoriety”.⁷⁷² These concerns extend beyond the material to the spiritual plane, as revealed by the following prayer: “San Roque, San Roque, que este perro no me toque!” This supplication for protection to the patron saint against pestilence, taught to children in both the Old and the New World for invocation whenever they encountered a dog on the street, literally translates to “St. Roque, St. Roque, do not allow this dog to touch me!”—classically linking dogs, bites, and resulting misfortune.

Ancient civilizations were familiar with rabies. An early passage mentions the dangers of dog bites, in the pre-Mosaic

^aSequences do not compose the complete genome.

Eshnunna Code of Mesopotamia, circa the 23rd century BC: “If a dog is mad and the authorities have brought the fact to the knowledge of its owner; if he does not keep it in, and it bites a man and causes his death, then the owner shall pay two-thirds of a mina [40 shekels] of silver”.⁴¹ In *The Iliad* (700 BC), Hector is compared to a rabid dog. Chinese scholars warned of the dangers of rabid dogs in 500 BC, and Aristotle (4th century BC) correctly associated the disease with animals but erroneously exempted humans from contracting it from a mad dog’s bite. In Rome, Cordamus guessed that a poison (i.e., a “virus”) was present in saliva. Similarly, in the 1st century AD, another Roman, Celsus, described clinical aspects of human infection: “The patient is tortured at the same time by thirst and by invincible repulsion toward water.” For prevention, he recommended immediate excision of the bitten tissue, cauterization of the wound by a hot iron, and dunking the victim into a pool. The Hebrew Talmud, also dating from the 1st century, makes several references to the disease. Throughout the ages, ingestion of a wide variety of substances (e.g., the liver from a mad dog, crayfish eyes, a cock’s brain or comb, or the cast slough of snakes pounded in wine with a male crab) and carrying sacred talismans or “madstones” were believed to be cures for rabies.⁴¹

The transition from the medieval era to the Renaissance period of pragmatism and experimentation resulted in a remarkable treatise in 1546, entitled “The Incurable Wound,” by Fracastoro. This Italian physician clearly stated that human beings are susceptible to rabies, and he vividly described a clinical case:

Its incubation [following a bite by a rabid animal] is so stealthy, slow and gradual that the infection is very rarely manifest before the 20th day, in most cases after the 30th, and in many cases not until four or six months have elapsed. There are cases recorded in which it became manifest a year after the bite. [Once the disease takes hold,] the patient can neither stand nor lie down; like a madman he flings himself hither and thither, tears his flesh with his hands, and feels intolerable thirst. This is the most distressing symptom, for he so shrinks from water and all liquids that he would rather die than drink or be brought near to water; it is then that they bite other persons, foam at the mouth, their eyes look twisted, and finally they are exhausted and painfully breathe their last.³⁶⁰

His portrayal of human rabies is accurate in that the incubation periods can extend from months to years after initial exposure,⁶⁶² but a biting attack on others by a rabid patient with resultant disease is an uncommon event.²¹⁸

Although rabies is known to have been widespread in the Old World for thousands of years, its occurrence in the New World is less understood because of a dearth of records before European arrival. Rabies in the Americas was reported by the Reverend Marmolejo in Mexico as early as 1709, but some suspect that it was present before Columbus’s arrival in the 15th century. For example, not long after the discovery of the Americas, the bishop Petrus Martyr-Anglerius wrote in his *De Rebus Oceanicis et de Orbi Novi* Decades Octo, “In several places bats not much smaller than turtle doves used to fly at them [the Spanish sailors and soldiers] in the early evening with brutal fury and with their venomous bites brought those injured to madness . . . [and] bats . . . come in from the marshes on the river and attack our men with deadly bite”.³⁸⁸ This may

have been one of the first descriptions of rabies transmission by vampire bats.

The bite of a rabid animal was considered a likely source of rabies infection by many, but it was only in 1804 that Zinke used dog saliva for transmission.³⁸⁶ Later in 1879, Galtier is credited with experimental rabies transmission and serial passage in rabbits.³⁸⁶ Clinical descriptions formed the basis for diagnosis until the advent of light microscopy. A clear description of viral and neuronal interactions was made by Negri in 1903, with the detection of cytoplasmic inclusions (Negri bodies) in neurons of rabid animals.³⁹³ Although the diagnostic value of Negri bodies was established by 1913, their viral composition had to wait until the later development of electron microscopy.

Pasteur’s research on rabies is perhaps the most well-known historical achievement in the field. First, through adaptation of “street” (wild-type) virus to laboratory animals, he was able to change its properties. Today, one could apply the term *attenuated* to his “fixed” virus strains. Second, Pasteur and his team developed concepts and experimental approaches to the first protective vaccination against rabies.³⁸⁸ Desiccated spinal cords from rabies virus–infected rabbits became the first rabies vaccine, and they were supposedly safe, although now it is known that the fixed viruses from which these vaccines were derived were not apathogenic but could actually cause the disease. July 6, 1885, is a milestone in the history of rabies. On that day, 9-year-old Joseph Meister was bitten at multiple sites by a rabid dog and received the first postexposure prophylaxis with Pasteur’s vaccine. Remarkably, Joseph survived.³⁸⁶ Pasteur’s vaccine, with all its modifications, became the accepted rabies prophylactic throughout the world in the early 20th century. Problems remained, however, because improperly inactivated virus caused rabies, and animal brain tissue induced allergic reactions leading to neuromuscular accidents. Moreover, the vaccine was not very effective in cases of severe bites, such as those inflicted on the face and neck by rabid wolves and dogs.

Postexposure prophylaxis against rabies through simultaneous administration of antirabies serum and vaccine was introduced in 1889 by Babes.²⁹ This approach found few adherents and languished until about 1940, when interest in the use of serum-containing rabies virus (RABV) antibodies was revived. In a trial organized by the World Health Organization in 1954, the combined use of serum and vaccine was found to be more protective than vaccine alone,²⁸⁸ an observation later corroborated by Chinese findings.²¹² Today, the combination of immune globulin and vaccine is the recommended standard for prophylaxis in human rabies exposure.

In the 1960s, an RABV grown in human diploid cells was used to produce a safe and efficacious inactivated vaccine,^{385,386} eliminating many of the problems connected with vaccines produced in brain tissue. This vaccine and others derived from cell culture are used widely throughout the world, although for economic reasons, several developing countries still use nervous tissue vaccines. Other RABV strains are used for vaccine production for human and animal use in addition to the original Pasteur virus (PV) strain. Given the progress in biotechnology, improved versions of rabies vaccines are currently under development.

Vesiculoviruses

Vesicular stomatitis virus (VSV) is the best-studied member of the genus *Vesiculovirus*. The extensive body of knowledge about

the replication of VSV reflects its status as a widely studied prototype for the nonsegmented, negative-strand RNA viruses. VSV produces an acute disease in cattle, horses, and pigs characterized by fever and vesicles in the mucosa of the oral cavity and in the skin of the coronary band and teat. Clinically, VS is very similar to foot-and-mouth disease (FMD). VSV can also cause an acute febrile disease in humans. Laboratory-adapted strains, however, are rarely pathogenic for humans.

Although VS was first reported in the United States in 1916 during an epidemic in cattle and horses,⁶⁹⁵ a clinically similar disease was previously described in army horses in 1862, during the U.S. Civil War.⁴⁸⁴ In 1915, French veterinarians described a disease clinically similar to VS in horses imported to Europe from the United States and Canada during World War I. At that time, the etiology of this disease could not be determined with certainty, but it could be transmitted from horse to horse by rubbing the saliva of a sick animal on the tongue of a healthy one, establishing the infectious nature of the disease.²⁹⁵ In 1925, cattle transported from Kansas City, Missouri, to Richmond, Indiana, initiated an outbreak of VS in the area. The disease was experimentally transmitted to horses and the infectious agent was maintained by serial passages in animals. This strain became the VS-Indiana virus (VSIV) strain.¹⁴⁹ In 1926, an outbreak of VS in cattle occurred in New Jersey. The causative agent was found to be a filterable agent that could infect cattle, horses, and guinea pigs. This virus, serologically different from the VSIV strain, is currently known as the VS-New Jersey virus (VSNJV) strain.^{148,149}

The VSIV and VSNJV viruses represent the two serotypes most commonly isolated in the Americas. Most of the commonly studied laboratory-adapted strains of VSV (e.g., Glasgow, Orsay, San Juan, Mudd-Summers) belong to the VSIV serotype. In the United States, the last reported outbreak of the VSIV serotype occurred in 1965.⁷⁵¹ The VSNJV serotype was responsible for outbreaks in the United States in 1944, 1949, 1957, 1959, 1963, 1982–1983, 1985, and 1995.⁸⁷ In 1997, isolated cases were diagnosed in several horses in New Mexico, but this did not initiate an outbreak.²¹ Between 1946 and 1954, during an outbreak of FMD in Mexico,²⁷⁰ the joint Mexico–American commission for the control of FMD developed techniques for the differential diagnosis of FMD and VS based on the isolation of the agent and complement fixation methods.²⁹⁵ The availability of a more efficient diagnostic methodology demonstrated that VS was prevalent throughout the year in the tropical areas of Mexico.²⁹⁵

In South America, the disease was reported in 1939 in La Plata, Argentina.²⁹⁵ Later, VSV was isolated in Barinas, Venezuela, in 1941, and in Colombia in 1943.²⁹⁵ Currently, VSV is endemic in many Latin American countries and is responsible for important economic losses in the livestock industry. Disease caused by VSV was reported in 11 countries of Latin America in 1996.⁷⁸⁸ Although the presence of VS was previously suggested in Africa in 1884 to 1887 and in Asia in 1944,²⁹⁵ presently the disease is considered enzootic only in the Americas.⁷⁸⁸

Other vesiculoviruses are endemic in the Americas, Asia, and Africa. Piry virus was isolated from an opossum (*Philander opossum*) in Brazil in 1960⁷⁰¹ and caused a febrile disease in humans.⁴⁷⁴ Cocal virus (COCV, or Indiana 2) was isolated from mites of the genus *Gigantolaelaps* from rice rats (*Oryzomys laticeps velutinus*) trapped during 1961, on Bush Bush Island in the Nariva swamp in eastern Trinidad.³⁵⁴ The VS Alagoas virus

(VSAV, or Indiana 3) was isolated from domestic animals in the state of Alagoas, Brazil, during a VS outbreak.⁷⁰⁰ Later it also was isolated from sand flies and seropositive (but otherwise healthy) livestock in Colombia.⁷⁰⁰ Maraba virus (MARAV) was isolated from sand flies (*Lutzomyia* sp.) collected in the state of Pará, Brazil. Although humans are infrequently infected based on serology, the actual public health significance of MARAV has not been assessed.⁷⁰⁹

Vesiculoviruses endemic in Asia include Chandipura virus (CHPV) and Isfahan virus (ISFV). ISFV was isolated from sand flies (*Phlebotomus papatasi*) collected in Dormian, Isfahan Province, Iran, in 1975.⁶⁹⁹ From serologic analyses, the presence of ISFV has been detected in India, Iran, Turkmenistan, and other Asian countries.⁴⁷⁴ CHPV was obtained from the sera of two patients with a febrile illness in Nagpur City, Maharashtra State, India, in 1965 during an epidemic of chikungunya and dengue.⁶⁶ This virus was also isolated from phlebotomine sand flies in West Africa in 1991.²⁴³ CHPV is now known to be a cause of viral encephalitis in children, following its identification as the cause of two recent outbreaks. One outbreak in 2003 in Andhra Pradesh State, India,⁵⁸⁰ included 329 cases (183 fatalities), and another in 2004 in Gujarat State, India,¹¹⁴ included 26 cases (at least 18 fatalities).

Several vesiculoviruses infect fish, and at least one of these, Spring viremia of carp virus (SVCV), has been recognized as a species of the *Vesiculovirus* genus. Dating back possibly to the Middle Ages, common carp *Cyprinus carpio* in European pond culture have been plagued by a complex of infectious diseases variously known as infectious dropsy, rubella, infectious ascites, hemorrhagic septicemia, and red contagious disease.^{59,316,621,706} These diseases proved to be of great economic importance, causing serious losses in carp pond fisheries of the central and eastern parts of Europe.^{227,228} The proposed causes (nutrition, environment, parasites, bacteria, viruses) for the acute and chronic forms of the epizootics remained controversial for a long time. However, a viral etiology for the acute form of infectious dropsy became evident when a cytopathic agent was isolated,⁷⁰⁶ and River's postulates were fulfilled using virus isolated from affected carp.²²⁹ In order to distinguish the viral disease from other etiologic entities within the infectious dropsy complex, the disease was renamed spring viremia of carp (SVC), and the causative virus was termed SVCV (or, initially, *Rhabdovirus carpio*).²²⁹

SVCV has been identified in different parts of Europe, Russia, and the Middle East, causing mortality of up to 70% of young carps.^{9,58,61,99,229,645,698,706} In 2002, SVCV was first reported in U.S. waters at a North Carolina koi hatchery. Unfortunately, there is evidence that koi had been distributed from this hatchery to most of the 48 contiguous states before being confirmed with SVC. The first common carp die-off of wild fish that tested positive for SVC occurred in 2002 at Cedar Lake, Wisconsin,¹⁸³ and the virus has rapidly disseminated to other states.

Ephemeroviruses

The first reference to bovine ephemeral fever (BEF) can be found in the book *The Heart of Africa*.⁶³⁶ Not until the 20th century was the disease reported among ruminants in much of its natural range throughout the tropical and subtropical regions of Africa, Asia, Australia, and the Middle East.⁶⁷¹ The apparent emergence and re-emergence of BEF over 125 years is likely due to the expansive growth of the cattle industry and

improved surveillance.⁷³⁵ Until 1966, when bovine ephemeral fever virus (BEFV) was grown in mice,⁷²³ research on the agent was restricted largely to transmission studies in cattle.¹³⁴ Characterization of ephemeroviruses is an ongoing process. For example, viruses Obodhiang (Sudan, 1963) and Kotonkan (Nigeria, 1967), isolated from mosquitoes, were initially suggested as “rabies related,” based on a limited antigenic cross-reactivity with lyssaviruses.⁶⁰ However, gene sequencing and phylogenetic reconstructions demonstrated that these viruses belong to ephemeroviruses.⁴⁰¹ Likely, more members of the genus will be recovered among other rhabdoviruses, isolated decades ago and awaiting molecular characterization.

Novirhabdoviruses

Infectious hematopoietic necrosis virus (IHNV) was first discovered in sockeye salmon (*Oncorhynchus nerka*) dying at hatcheries in Washington in 1953.⁶¹¹ Similar outbreaks among hatchery-reared salmonid fish in California were reported in the following decades.^{285,777} It was thought that IHNV was confined to salmonid fish in the Pacific coast of North America.⁴⁸² However, the virus spread during the 1970s to the eastern United States, Europe, Japan, Korea, Taiwan, and China by shipment of infected fish and eggs.^{85,418,617} Electron microscopy of IHNV particles along with physicochemical and serologic analysis demonstrated that IHNV is a member of the *Rhabdoviridae*.^{16,314,483} Gene sequencing demonstrated that IHNV has the five structural genes common to rhabdoviruses, with the addition of a nonstructural, nonvirion (NV) gene between the genes for the G and L proteins.³⁹⁹ Several more fish rhabdoviruses, which demonstrate similar pathobiology and have similar genome organization, have been described, including Hirame rhabdovirus, snakehead virus, and viral hemorrhagic septicemia virus. These viruses were identified not only in North America but also in eastern and southern Asia, where they appear to be endemic.^{363,374} These viruses were first assigned into the genus *Novirhabdovirus*, based on the presence of the NV gene, in the Seventh Report of the International Committee on Taxonomy of Viruses (ICTV).⁷³⁶

Sigma Virus

This virus, a natural pathogen of *Drosophila* spp. fruit flies, was described in 1937.⁴⁰⁷ Sigma virus appears to be distributed worldwide. This is the only arthropod-specific rhabdovirus described to date, with an unusual mode of transmission: it is only transmitted vertically through both eggs and sperm and does not move horizontally between hosts.¹⁴⁵ Sigma virus was initially placed in the *Rhabdoviridae* based on its bullet-shaped viral particles,^{64,696} and this has subsequently been confirmed using sequence data.⁷¹ Initially it was believed that Sigma virus infects only *D. melanogaster*. However, additional surveillance identified recently that related variants of Sigma virus infect *D. affinis* and *D. obscura*.⁴⁵¹

TAXONOMY

The rhabdoviruses share a variety of gross morphologic and functional attributes with other members of the order *Mononegavirales*. For example, the virions are large structures that mature by budding, with membrane-bound spikes and a helical nucleocapsid. They possess single-stranded, nonsegmented,

negative-polarity RNA, with a similar gene arrangement. Within the family, recent analyses support the concept of a unified phylogeny and suggest an evolutionary history influenced by host species and transmission dynamics.^{83,404} Currently, the ICTV recognizes four genera of animal rhabdoviruses and two genera of plant rhabdoviruses. Furthermore, several rhabdovirus species have been recognized without inclusion into any of the established genera.¹⁷⁷ Figure 31.1 shows phylogenetic relationships among rhabdoviruses.

Within the genus *Lyssavirus* only one major serogroup had been established, although various serotypes were defined.⁶¹³ Placement within the genus was determined by serologic cross-reactivity of viral antigens, primarily based on antigenic sites on the nucleoprotein (the N protein). Historically, placement of a species as a rabies or rabies-related virus was determined by recognition of antigenic sites of the glycoprotein (the G protein) via virus neutralization tests. As nucleotide sequence data became available for a number of other *Lyssavirus* species,^{44,84,173,377,400,402,405,663} a trend toward genetic classification was established. Currently ICTV recognizes 11 *Lyssavirus* species, and one more representative (*Shimoni bat virus* [SHIBV]) is included in the genus provisionally without established species status (Table 31.1).

In general, demarcation criteria for *Lyssavirus* species include the following: (1) Genetic distances, with the threshold of 80% to 82% nucleotide identity for the complete N gene or 80% to 81% nucleotide identity for concatenated coding regions of N+P+M+G+L genes. Globally, all isolates belonging to the same species have higher identity values than the threshold, except the viruses currently included into the *Lagos bat virus* (LBV) species. For that reason some authors suggested that LBV be subdivided into several genotypes.^{173,473} However, as these LBV representatives are segregated into a monophyletic cluster in the majority of phylogenetic reconstructions, in the absence of other sufficient demarcation characters there is currently no possibility to subdivide LBV into several viral species. (2) Topology and consistency of phylogenetic trees, obtained with various evolutionary models. (3) Antigenic patterns in reactions with antinucleocapsid monoclonal antibodies (preceded by serologic cross-reactivity and definition of *Lyssavirus* serotypes, using polyclonal antisera). (4) Whenever available, additional characteristics, such as ecological properties, host and geographic range, and pathologic features, are considered.¹⁷⁷ Moreover, based on genetic distances and serologic cross-reactivity, the genus has been subdivided into two phylogroups. Phylogroup I includes RABV, *European bat Lyssavirus type 1* (EBLV-1), EBLV-2, *Duvenhage virus* (DUVV), *Australian bat Lyssavirus* (ABLV), *Aravan virus* (ARAV), *Khujuand virus* (KHUV), and *Irkut virus* (IRKV). Phylogroup II includes LBV, *Mokola virus* (MOKV), and SHIBV. The remaining species of the genus, *West Caucasian bat virus* (WCBV), cannot be included in either of these phylogroups and is suggested to be considered as a representative of independent phylogroup III.^{400,402}

Based on the serologic cross-reactivity patterns and sequence analyses of the members of the genus *Vesiculovirus*, a unique VSV serogroup has been established. This serogroup includes VSIV (currently the type species of the genus), VSJNV, VSAV, *Carajas virus*, CHPV, COCV, ISFV, MARAV, and *Piry virus*.¹⁷⁷ Also recognized as a *Vesiculovirus* species is SVCV. Furthermore, 19 viruses are provisionally included in the genus without established species status (Table 31.1).

FIGURE 31.1. Phylogenetic relationships among rhabdoviruses.

The members of the genus *Ephemerovirus* show limited cross-neutralization reactivity, but they are highly cross-reactive in complement fixation or indirect immunofluorescence tests. They exhibit similar but distinct genome organization with the common feature of a nonstructural glycoprotein (G_{NS}) gene but variations in the number of accessory protein genes and the location of transcriptional control sequences. Different species may share up to 91% identity in N protein amino acid sequence. Currently the genus includes only three recognized species, but five more viruses are included provisionally¹⁷⁷ (Table 31.1), based on antigenic reactivity and phylogenetic analysis of limited gene fragments.^{83,401} Phylogenetic relationships indicate that several intercontinental translocations of ephemeroviruses are likely to have occurred. Adelaide River virus (ARV) (Australia) and Obodhiang virus (OBOV) (Africa) demonstrate more genetic identity to each other than is observed between ARV and BEFV, both circulating in Australia. BEFV also circulates broadly in Africa, the Middle East, and southern areas of Asia, without significant genetic diversity.^{401,404,735}

The genus *Novirhabdovirus* was established based on the presence a small NV protein of unknown function. The NV open reading frame (ORF) is located between the G and L genes and is preserved in diverse viruses and strains. The NV protein sequences are significantly less conserved between viruses in different species than sequences of the structural proteins.^{317,398}

Species within the genus have been distinguished serologically on the basis of cross-neutralization with polyclonal rabbit antisera. Thus, IHNV and hirmine rhabdovirus (HIRRV) each constitute single serotypes, and viral hemorrhagic septicemia virus (VHSV) has one major serotype with a small number of associated strains. Viruses from different species do not show cross-neutralization, but in some cases there is a low level of cross-reaction with specific proteins in western blot analyses. Nucleotide sequence data are available for most genes of these viruses and will undoubtedly contribute to the distinction of viral species in the future. For strains within a virus species, the nucleotide sequence divergence ranges up to a maximum of 8% for IHNV G and NV genes and 18% for the G genes of European and North American VHSV. N protein amino acid identity between IHNV and VHSV is approximately 34%.¹⁷⁷

Members of two genera of the *Rhabdoviridae* infect plants and are transmitted via arthropod vectors, such as leafhoppers, planthoppers, and aphids.³⁴² The cytorhabdoviruses and nucleorhabdoviruses are primarily distinguished based on their sites of virion maturation, in the cytoplasm and the nucleus, respectively. Genus classification based on sequence diversity has thus far correlated with classification by intracellular virus maturation. The genus *Cytorhabdovirus* currently includes nine recognized species and three provisional members, whereas genus *Nucleorhabdovirus* includes nine and four members, respectively

(Table 31.1). There is no significant sequence similarity (>50%) between analogous genes of the different species analyzed to date. However, nucleotide sequences are available for only a limited number of representatives and at the moment cannot be considered as sufficient to demarcate different species.¹⁷⁷

Recently, several rhabdoviruses, previously referred to as “unclassified”,⁷⁰⁷ were recognized by the ICTV as species, without assignment to any particular genus, based on their unique genome structure, phylogenetic and antigenic properties, and sufficient amount of knowledge on their ecology or pathobiology. These include *Flanders*, *Tupaia*, *Sigma*, *Ngaingan*, and *Wongabel* viruses.¹⁷⁷ The recently described *Moussa virus*⁵⁷⁵ is another candidate for the establishment of a viral species without inclusion in any recognized genus.

VIRION STRUCTURE

Rhabdoviruses are enveloped, rod- or cone-shaped particles (Fig. 31.2A, B), approximately 100 to 430 nm long and 45 to 100 nm in diameter. Animal rhabdoviruses are usually approximately 180 nm long and 80 nm wide, but those isolated from plants can be longer. The length of the virion is dictated by the length of the RNA genome, so that incorporation of additional genes into the viral genome results in correspondingly longer virions.⁶²⁹ Typically, mature virions appear either as bullet-shaped particles with one rounded and one flattened end or as bacilliform particles that appear hemispheric at both ends.

The genome RNAs of VSV and RABV, which are 11 to 12 kb, are encapsidated by approximately 1,200 copies of a

single major nucleoprotein (N protein), with each molecule of N protein covering nine bases.^{277,702} Unlike the paramyxovirus *rule of six*, there is no requirement that the genome size be a multiple of this number. The nucleocapsid also contains 466 copies of the phosphoprotein (P protein, formerly called NS protein)⁷⁰² and 50 copies of the large polymerase protein (L protein), which are responsible for the virion-associated RNA polymerase activity. The viral RNA polymerase cannot use naked RNA as a template but instead requires that the virion RNA template be encapsidated by N protein. P protein is responsible for binding L protein to the N protein–RNA template, and L protein is likely responsible for all of the enzymatic activities associated with RNA synthesis.

The structures of N protein–RNA complexes from RABV and VSV have been determined by x-ray crystallography.^{11,276} The N protein molecule consists of two lobes, with the RNA inserted between the two lobes (Fig. 31.3). In the nucleocapsid, an amino-terminal extension from each N protein subunit interacts both with the adjacent subunit and with the subunit two positions away (Fig. 31.3, inset). Contacts between the C-terminal lobes also contribute to the stability of the nucleocapsid. N protein forms a stable nucleocapsid-like structure even in the absence of RNA.^{278,810} The C-terminal lobes of two N protein molecules in the nucleocapsid form a binding site for the P protein polymerase subunit, which is proposed to bind and dissociate in a processive manner during RNA synthesis.²⁷⁶

P protein consists of three domains, an acidic N-terminal domain, a central domain, and a C-terminal domain.¹⁸⁵ P protein forms homo-oligomers, which are necessary for P protein to bind L protein to the nucleocapsid and for subsequent

Model of N protein and RNA in the VSV nucleocapsid derived from x-ray crystallography²⁷⁹ and cryoelectron microscopy.²⁶⁴ **Inset** shows interaction of the N-terminal extension from the pink N protein subunit with the C-terminal domain of the adjacent subunit (blue) as well as the subunit two positions away (white). (Assembled from PDB file 2WYY (MMDB ID: 80066) using Cn3D4.2 software.)

transcriptase activity.^{256,257} The oligomerization is mediated by the P protein central domain, the structure of which has been determined by x-ray crystallography.¹⁸⁴ Both the isolated central domain and the unphosphorylated full-length P protein form dimers.^{184,267} The phosphorylated transcriptionally active form of P protein was originally considered to be a trimer, based on epitope dilution experiments.²⁵⁶ Reanalysis of those data,⁶⁹³ however, suggests that P protein forms tetramers, similar to the P proteins of paramyxoviruses. Much of the N-terminal domain of P protein appears to be intrinsically disordered, although it probably adopts a well-defined structure upon binding ligands such as the L protein or soluble N protein (N_0) involved in encapsidation of progeny genomes during genome replication.^{268,434} Two sites in the N-terminal domain must be phosphorylated by cellular casein kinase II for P protein to form oligomers and act in transcription.^{257,689} The C-terminal domain is responsible for binding the P protein to the nucleocapsid template, as described earlier. A basic region near the C-terminus of P protein is also necessary for interaction with L protein in viral transcription.¹⁶⁴ The structures of the C-terminal domains of RV and VSV P proteins have been determined by x-ray crystallography and NMR spectroscopy.^{276,481,588}

The organization of the L protein has been deduced by analysis of sequence homology among members of the order *Mononegavirales*, which identified six conserved regions designated CRI through CRVI. The RNA polymerase activity has been mapped to CRIII.⁶⁵⁵ The L protein also has messenger RNA (mRNA) capping and methylation activity, which map to CRV⁴³⁷ and CRVI,⁴³⁵ respectively. High-resolution structures of L protein have not been published thus far, but its domain organization has been determined by negative stain electron microscopy combined with proteolytic digestion and deletion mutagenesis.⁵⁷⁷ The protein is organized into a ring-like structure that contains the RNA polymerase and an appendage of three globular domains. The capping activity maps to a globular domain attached directly to the ring, and the methylation activity maps to a more distal and flexibly connected domain.

When released from virions by treatment with detergents at high ionic strength, the nucleocapsid is loosely coiled and flexible (Fig. 31.2C), with a total length of 3.6 μm .⁷⁰² In virions, however, the nucleocapsid is associated with the matrix (M) protein, which condenses the nucleocapsid into a tightly coiled helical nucleocapsid–M protein complex (Fig. 31.2D), sometimes referred to as the virus *skeleton*,^{54,514,515} which gives

the virion its bullet-like shape.^{54,463,514,515} The structure of the nucleocapsid–M protein complex has been determined to 10.6 Å resolution by analysis of cryoelectron micrographs of VSV virions (Fig. 31.2E).²⁶⁴ The N and M protein subunits in this structure were identified by fitting the electron density data from electron microscopy to that from x-ray crystallography. The N protein and RNA form an inner helical layer surrounded by an outer helical layer composed of M protein. The orientation of N protein subunits indicated that the 5′ end of the genome RNA is at the tip of the bullet, and the 3′ end is at the base. The conical tip of the bullet is formed by approximately seven successive turns of the N protein helix expanding gradually from 10 subunits per turn to 37.5 subunits per turn, with two turns forming a helical repeat. This pattern continues for approximately 29 turns to form the cylindrical trunk of the bullet. The M protein layer is formed by interaction of each M protein subunit with two successive turns of the N protein helix. The helical structure is held together by the M–N interactions as well as the interaction between M protein subunits in successive turns of the helix.

The amino-terminal 50 to 57 amino acids of M protein appear to be largely disordered in purified M protein.^{260,274,362} However, this sequence may form an ordered structure upon binding to the nucleocapsid.²⁶⁴ The remainder of the M protein sequence forms a compactly folded C-terminal domain, whose structure has been determined by x-ray crystallography.^{261,274} Sequences in the amino-terminal region are involved in interaction with N protein in the nucleocapsid–M protein complex, as well as interacting with sequences in the C-terminal domain in M–M interactions in the complex.^{144,160,264,274} The C-terminal domain of M protein also appears to interact with the virus envelope, perhaps with the cytoplasmic domain of the envelope glycoprotein.²⁶⁴

The structure derived from cryoelectron microscopy accounts for approximately 1,200 of the 1,800 copies of M protein in the virion. The remaining 600 M protein subunits are likely present in a nonhelical arrangement, thus rendering them undetectable in the analysis. One likely location is in association with the envelope lipid bilayer. M protein interacts with the lipid bilayer of the virus envelope, which was shown using lipophilic photoreactive probes.^{430,804} The M protein sequences involved in the interaction are present in the N-terminal region, partially overlapping the sequences involved in interaction with the nucleocapsid.^{160,430} This supports the idea that there are two populations of M protein in the virion, one involved in the nucleocapsid–M protein complex and the other involved in interaction with the envelope lipid bilayer.

The lipids of the envelope are derived from the host cell membrane during virus assembly by budding. The lipid composition of the envelope generally reflects that of the host membrane from which the virus buds, consisting primarily of phospholipids and cholesterol, although virus envelopes appear to be enriched in cholesterol and sphingomyelin compared with the host membranes from which they were derived.⁴⁵⁵ The virus envelope contains approximately 300 to 400 spike-like projections composed of a single species of viral glycoprotein (G protein). The individual spikes are trimers of G protein,^{188,262,765} which function in virus attachment and penetration by fusion of the virus envelope with endosome membranes. G protein is anchored in the envelope lipid bilayer by a 20–amino acid hydrophobic transmembrane domain near the

C-terminus, which is followed by a 29–amino acid *cytoplasmic domain*, which is inside the virus envelope.⁶⁰⁶ The structure of the 446–amino acid external domain (ectodomain) of the VSV G protein has been determined by x-ray crystallography in both the neutral pH (“prefusion”) and low pH (“postfusion”) conformations (Fig. 31.4).^{595,596} Like other viral fusion proteins, the two conformations are dramatically different, indicating that major structural rearrangements must occur during

FIGURE 31.4. Structure of the vesicular stomatitis virus (VSV) G protein. **A:** G protein ectodomain trimers in the prefusion and postfusion state. G protein ectodomain (residues 1 to 422) was generated by limited proteolysis of virions with thermolysin.^{595,596} **B:** Comparison of domain organization of a single G protein subunit in the pre- and postfusion states. **C:** Diagram of domain rearrangements in transition from prefusion state (1) to proposed intermediate inserted into target membrane (2) to postfusion state (3). White line represents G stem leading to membrane anchor sequence that is missing from the crystal structure. (Assembled from PDB files 2CMZ and 2J6J using Cn3D4.2 software.)

the fusion process. The surprising result is that the folding of G protein bears no resemblance to the fusion proteins of other negative-strand or positive-strand RNA viruses that have been determined. Instead, the structure of the VSV G protein is homologous to that of the gB glycoprotein of herpesviruses.³⁰⁵ This raises interesting questions about the evolutionary origin of these proteins.

GENOME STRUCTURES

Genomes of rhabdoviruses are single-stranded, nonsegmented RNA of negative polarity. They lack 5' caps and 3' poly A, consistent with their inability to function as mRNA. Genomes of three genera of *Rhabdoviridae* are shown diagrammatically in Figure 31.5. Genomes of lyssaviruses and vesiculoviruses are similar to each other. The approximately 50 nucleotides at the 3' and 5' ends (the leader and trailer sequences, respectively) are partially complementary. They contain important *cis*-acting sequences that serve as promoters for transcription and replication and as signals for encapsidation of genomes and anti-genomes during replication, as described later. Although they do not encode proteins, short RNAs of unknown function are generated from these sequences. The five protein-encoding genes are in the order 3'-N-P/C-M-G-L-5', which is the order of the analogous genes in other nonsegmented, negative-strand RNA viruses, regardless of the number of additional viral genes. Each gene junction contains a conserved sequence specifying the end (E) of the upstream gene, a two-nucleotide intergenic (I) sequence, and the start (S) sequence for the downstream gene. These sequences control the activities of the viral RNA polymerase, which transcribes these genes according to a stop-start mechanism described later. In general, the 5' and 3' untranslated regions of the viral mRNA are short (10 to 50 nucleotides) and lack *cis*-acting sequences that control translation or mRNA turnover. The one exception is the P/C gene of vesiculoviruses, which contains alternate start codons. The upstream start codon initiates translation of the P protein, whereas two downstream start codons initiate translation of an alternate reading frame that encodes two small basic proteins, C and C'.^{392,667} Analogous proteins encoded by paramyxoviruses often play a role in pathogenesis by altering viral gene expression and suppressing host responses to virus infection. Mutation of the VSV P gene to introduce a stop codon in the C and C' open reading frame (without altering the sequence of the P protein), however, had no detectable effect on virus replication in cell culture or pathogenesis in mice.³⁹²

This still leaves open the possibility that the C and C' proteins play a role in replication in other hosts.

The genomes of ephemeroviruses are larger than those of most other rhabdoviruses. The genome of BEFV is 14.8 kb and contains 10 genes (3'-N-P-M-G-G_{NS}-α₁-α₂-β-γ-L-5') separated by intergenic regions of 26 and 53 nucleotides.^{177,735} The genome of the related Adelaide River virus is 14.6 kb in length and contains nine genes (3'-N-P-M-G-G_{NS}-α₁-α₂-β-L-5') separated by intergenic regions of one to four nucleotides.⁷⁴² The G_{NS} gene encodes a glycoprotein, which is synthesized in approximately the same amount as G protein during virus infection,⁷³⁷ but it is not found in the mature virion. Intracellularly, G_{NS} protein is localized in the endoplasmic reticulum-Golgi complex, and it is associated with amorphous structures in the cell surface but not with viruses in the budding process. It is highly glycosylated, with a molecular weight of 90 kD. G_{NS} protein shares significant amino acid sequence homology with the G protein, but it does not induce *protective* neutralizing antibodies.³¹² The function of G_{NS} protein is unknown. It has been proposed that the gene coding for this protein originated by gene duplication by a copy-choice mechanism involving relocation of the polymerase in an upstream position during viral replication.⁷⁴²

Genomes of novirhabdoviruses contain an NV gene between the G and L genes. The NV protein (12 to 14 kD) is expressed at variable levels in infected cells but is not detectable in purified virions. The NV protein sequences are significantly less conserved between viruses in different species than sequences of the other structural proteins, such that there is no significant amino acid sequence similarity between the NV proteins of IHNV and VHSV. The specific function of the NV protein is not yet defined, but it is required for efficient virus replication. Results of studies with NV gene deletion mutants generated by reverse genetics are inconsistent in that the NV appears to be required for pathogenicity in IHNV and VHSV but not snakehead virus (SHRV).^{317,398}

Rhabdoviruses that have not been assigned to a particular genus have a variety of additional transcription units. For example, the gene order of FLAV is 3'-N-P-pseudogene 1-19K-pseudogene 2-M-G-L-5'. The unique features include the gene encoding a 19-kD protein of unknown function, surrounded by two pseudogenes, about 500 nucleotides each, situated between the P and M genes.^{86,177} The gene order of TUPV is 3'-N-P/C-M-SH-G-L-5'. The unique small hydrophobic (SH) transcription unit between M and G genes encodes a protein with two hydrophobic amino acid stretches, including a potential signal sequence at the amino terminus

Vesiculovirus and lyssavirus

Novirhabdovirus

FIGURE 31.5. Diagram of rhabdovirus genomes.

and a potential membrane-spanning sequence near the center. The C protein ORF that overlaps the TUPV P gene has the potential to encode a 221-amino acid basic protein that is more than three times larger than the VSV C protein.⁶⁶⁸

The genome of Ngaingan virus (NGAV) is over 15.7 kb, which is the largest genome yet described for any rhabdovirus, containing 13 ORFs in the order 3'-N-P-U1-U2-U3-M-U4-G-G_{NS}-U5-U6-U7-L-5'. The NGAV P gene contains two alternative ORFs designated P1' and P2', analogous to alternative P ORFs referred to as either C or P' in several other rhabdoviruses. The G_{NS} gene encodes a nonstructural glycoprotein (568 amino acids [aa]) analogous to that of ephemeroviruses. NGAV contains seven additional genes (U1 through U7) with the potential to encode small proteins of unknown function. Although similar in size (81 to 153 aa) to proteins encoded by ORFs located in similar positions in several other rhabdoviruses, they lack significant sequence or structural similarity to any known protein. However, none of the small unique NGAV proteins has yet been detected in infected cells.²⁸³

The gene order in WONV is 3'-N-U4-P-U1-U2-U3-M-G-U5-L-5'. WONV lacks an alternative ORF in the P gene but contains five additional genes (U1 through U5), each of which encodes a protein that lacks significant amino acid sequence identity with other known proteins. The U1 protein (179 aa) is hydrophilic with numerous potential phosphorylation sites, an N-glycosylation site, an amidation site, and two N-myristoylation sites. The U2 protein (192 aa) contains two predicted N-myristoylation sites and a highly hydrophobic domain of 10 amino acids followed by a mitochondrial energy transfer signature that is characteristic of carrier and transport proteins. The U4 protein (49 aa) contains a single putative N-myristoylation site and shares overall 49% identity with guanosine triphosphate (GTP)-binding proteins of several bacteria. The U5 protein (127 aa) contains a predicted N-terminal extracellular domain, 22-aa transmembrane domain, and highly basic cytoplasmic tail and has overall structural similarity to the α_1 proteins of ephemeroviruses, which have been suggested to be viroporins. Proteins of similar size

to the U1, U2, U3, and U5 proteins have been detected in WONV-infected cells by immunoblot analysis using polyclonal mouse ascitic fluid.²⁸⁴

The genome of Moussa virus is similar to those of the genera *Lyssavirus* and *Vesiculovirus*. However, the ORFs located in the position of the P (ORF 2) and M (ORF 3) genes in other rhabdoviruses show no nucleotide or amino acid homology to sequences of other rhabdoviruses.⁵⁷⁵

The genomes of Sigma virus and members in the genera *Cytorhabdovirus* and *Nucleorhabdovirus* contain an additional gene between the P and M genes, referred to as "X" or "a." The putative X protein is of unknown function but contains conserved domains found in reverse transcriptases. Another unusual feature is that M and G mRNAs overlap by 33 nucleotides.^{106,145}

STAGES OF REPLICATION

The replication cycle of rhabdoviruses is typical of that of most nonsegmented, negative-strand RNA viruses (Fig. 31.6). The initial events of attachment, penetration, and uncoating result in release of the viral nucleocapsid into the cytoplasm of the host cell. The encapsidated parental genome RNA serves as a template for primary transcription by the virion RNA-dependent RNA polymerase, resulting in synthesis of leader (le) RNA and all five viral mRNAs. The accumulation of viral proteins synthesized from primary transcripts leads to replication of the genome, which involves synthesis of full-length positive-strand RNA, or antigenomes. The antigenomes, in turn, serve as templates for synthesis of progeny negative-strand genomes. Encapsidation of genomes and antigenomes occurs concomitantly with their synthesis and, indeed, is a key signal for the RNA polymerase to function as a replicase versus a transcriptase. Progeny nucleocapsids are used for three different purposes: (a) as templates for further rounds of replication; (b) as templates for secondary transcription, which is the major amplification step for viral gene expression; and (c) for assembly into progeny virions, which occurs by budding

FIGURE 31.6. Diagram of rhabdovirus replication cycle. The steps illustrated are virus adsorption and penetration by endocytosis, envelope fusion and penetration by endocytosis, release of nucleocapsids containing parental genomes into the cytoplasm, primary (1-degree) transcription, genome replication to produce nucleocapsids containing antigenomes and progeny genomes, secondary (2-degree) transcription, and assembly by budding from host plasma membrane. (Drawn by E. Alexander Flood.)

from host membranes. In a single-cycle growth experiment, the early events including attachment, penetration, uncoating, and primary transcription occur within the first few hours postinfection. The processes of genome replication, secondary transcription, and virus assembly occur continuously throughout the remainder of the infectious cycle, which lasts for an additional 12 to 18 hours for VSV or several days for RABV.

Mechanism of Attachment

Rhabdoviruses appear to use a variety of different receptors for attachment to different types of host cells. The RABV G protein binds most effectively to cells of neuronal origin,⁷¹³ reflecting the neurotropism of RABV *in vivo*. Several different surface molecules expressed at high levels on neurons have been identified as potential receptors, including the nicotinic acetyl choline receptor,^{259,431} the neural cell adhesion molecule (CD56),⁷⁰⁴ and the low-affinity nerve-growth factor receptor p75^{NTR}.^{714,715} Expression of CD56 and p75^{NTR} has been shown to confer susceptibility to RABV on cells that are normally resistant to infection. Transgenic mice that lack CD56 show a delay in RABV spread through the central nervous system (CNS) and in RABV-induced mortality, but the mice still die following virus infection,⁷⁰⁴ indicating that other receptors are involved. RABV infection of transgenic mice that lack p75^{NTR} was found to be similar to that of wild-type mice of the same strain,³³⁹ initially indicating that p75^{NTR} was not an important receptor for RABV pathogenesis. However, RABV G protein binds to a region of p75^{NTR} that is present on a splice variant of p75^{NTR} that is still expressed in the transgenic mice.⁴¹⁴ Thus, further experiments are required to fully evaluate the role of p75^{NTR} in RABV pathogenesis.

In addition to the receptors that are enriched on cells of neuronal origin, RABV can also use receptors that are widely distributed among many cell types.^{582,685,793} These receptors appear to be of lower affinity than those on neuronal cell surfaces⁷¹³ and have been difficult to identify. A similar difficulty exists in identifying receptors for VSV, which also binds to many different cell types in culture by interactions that appear to be of low affinity and often are not easily saturable. For both RABV and VSV, negatively charged lipids have been proposed to be cellular receptors for virus attachment. In the case of RABV, neuraminic acid-containing glycolipids (gangliosides) have been implicated⁶⁸⁶ and, in the case of VSV, phosphatidyl serine has been proposed as a cellular receptor,⁶²⁴ although later experiments have indicated that phosphatidyl serine is not the receptor for VSV.¹³⁹ Instead, it seems likely that nonspecific electrostatic and hydrophobic interactions mediate attachment of VSV to cells. Treatment of cells with polycations and polyanions such as diethylaminoethyl-dextran (DEAE-dextran) and dextran sulfate can markedly enhance the efficiency of attachment and infection of cells by both VSV⁴⁵ and RABV.⁷⁹³

An interesting feature of attachment by both viruses is that binding is markedly enhanced at lower pH in the range from pH 6.5 to 5.6.^{248,793} The pH dependence of attachment is similar to that of envelope fusion with cellular membranes (discussed in the next section), although fusion occurs most efficiently at slightly lower pH than does virus attachment. Furthermore, G protein mutations that shift the pH dependence of fusion also shift the pH dependence of attachment.²⁴⁸ This suggests that attachment to many cell types is mediated by G protein in a conformation that is similar to the fusion-

active form of the viral G protein. This idea is supported by experiments with photoactivatable lipid probes, which indicate that the putative *fusion peptide* (described later) is inserted into target membranes under the optimal conditions for both attachment and fusion.^{197,542} This would also account for the affinity of the VSV G protein for phosphatidyl serine and other negatively charged phospholipids, because the presence of negatively charged lipids in the target membrane appears to be necessary for virus envelope fusion.^{105,199,796}

Mechanism of Penetration

VSV was one of the early examples of a virus shown to penetrate into cells by clathrin-dependent endocytosis.⁴⁷⁸ Following attachment to host cell surfaces, virions can either migrate to preformed clathrin-coated pits or nucleate the formation of new coated pits,^{157,348} where they undergo endocytosis into coated vesicles (Fig. 31.7). Because VSV virions are longer than the typical diameter of a coated vesicle, the final closure of the endocytic vesicle requires participation of the actin cytoskeleton.^{157,158} The endocytic vesicles lose their clathrin coats to become early endosomes. The contents of early endosomes are transported to late endosomes and lysosomes for degradation. During this process, the endosomal vesicles often invaginate to form multiple intraluminal vesicles.²⁸² Such membranes are referred to as *multivesicular bodies* (MVBs). As virions progress through the endocytic pathway, they are exposed to progressively lower pH. At a pH below 6.5, the G protein mediates fusion of the viral envelope with the endosome membrane. This fusion event releases the internal virion components into the cytoplasm (left side of Fig. 31.7). Most of the available evidence indicates that VSV virions fuse primarily with the membranes of early endosomes.^{348,498,648} Other evidence, however, suggests that many fusion events occur within MVBs (right side of Fig. 31.7), releasing the internal virion contents into the cytoplasmic contents trapped within the MVBs and requiring *back-fusion* of internal vesicles with the limiting membrane of the MVBs to release the viral nucleocapsid into the cytoplasm of the cell.^{422,460} Viral proteins that fail to be released into the cytoplasm are degraded by proteases and other enzymes in lysosomes.⁴⁷⁸

The mechanism by which rhabdovirus G proteins induce fusion of the virus envelope with cellular membranes shares many features with other viral envelope fusion proteins but is clearly distinct in several respects. The VSV G protein and the structurally similar fusion proteins of herpesviruses and baculoviruses are referred to as class III fusion proteins to distinguish them from class I proteins, which are structurally similar to the influenza virus hemagglutinin, and class II proteins, which include the envelope glycoproteins of the alphaviruses and flaviviruses.³² As with class I fusion proteins, rhabdovirus G proteins exist as a trimer of subunits held together by noncovalent bonds.^{188,262,765} Unlike most viral envelope proteins, however, the subunits of G protein are in a dynamic equilibrium between monomers and trimers because of the rapid dissociation and reassociation of subunits.^{464,801,802} As with most low pH-dependent fusion proteins, the effects of low pH are mediated by conformational changes in G protein. Unlike other viral fusion proteins, the conformational changes in G protein are reversible upon returning the pH to neutrality, whereas those of many other viral fusion proteins are not reversible.^{188,263,573}

FIGURE 31.7. Diagram of rhabdovirus penetration by endocytosis. Pathway on the **left** shows virus envelope fusion with early endosomes. Pathway on the **right** shows virus envelope fusion with internal vesicles of multivesicular bodies (MVBs) and release of nucleocapsids into the cytoplasm by "back-fusion" with the MVB-limiting membrane.

A general principle by which viral envelope proteins promote fusion is that they must insert into the target membrane through a region of their sequence referred to as the *fusion peptide*. In the class I fusion proteins, such as the influenza virus hemagglutinin (HA) and the paramyxovirus F proteins, the fusion peptide resides at the N-terminus of one of the subunits (HA₂ or F₁, respectively) generated by proteolysis of an inactive precursor. In contrast, proteolysis of rhabdovirus G proteins is not involved in activating fusion. This is similar to the case of the class II fusion proteins, in which the fusion peptide appears to be an internal region of the protein sequence. The regions of G protein that insert into target membranes at low pH have been mapped using photoactivatable lipid probes and mutagenesis studies in both the RABV and VSV G proteins.^{197,249,441,684,808} These sequences form two loops containing hydrophobic amino acids that extend from the protein structure ("fusion loops," Fig. 31.4A). In the neutral pH "prefusion" state, the fusion loops are oriented toward the viral membrane (Fig. 31.4A, B). Upon lowering the pH, there is a

proposed intermediate, in which the domain containing the fusion loops is reoriented to insert into the target membrane (Fig. 31.4C). Fusion of the viral and target membrane involves another domain rearrangement that brings the two membranes together in the "postfusion" state.

A second region of the G protein sequence functionally involved in fusion is the membrane-proximal ectodomain sequence immediately N-terminal to the membrane anchor sequence. Most of this sequence is not visible in the x-ray structures, because it was cleaved to solubilize the G protein. Mutations in this region dramatically inhibit fusion.^{347,647} G protein truncations containing part of this region (amino acids 421 to 461) together with the membrane anchor sequence and the cytoplasmic domain (*G stems*) enhance the fusion activity of other membrane fusion proteins and are able to cause hemifusion (mixing of the outer phospholipid leaflets of the two membranes) in the absence of other fusion proteins.³⁴⁷ The cooperation of the fusion loops and the membrane-proximal sequence may be analogous to similarly separate sequences in

other viral fusion proteins in bringing the viral and host membranes together for fusion.

Uncoating and Primary Transcription

Following fusion of the virus envelope with endosome membranes, which releases the internal virion components into the cytoplasm of the host cell, the viral M protein dissociates from the nucleocapsid.^{162,498,590} This step is necessary for viral RNA synthesis to occur, because M protein inhibits viral transcription.^{107,136,443,543,775} Binding of most of the M protein to nucleocapsids is readily reversible,⁴⁶¹ and dissociation following envelope fusion is believed to occur spontaneously, although acidification of the virion interior appears to promote M protein dissociation from the nucleocapsid, similar to the M1 protein of influenza virus.⁴⁹⁷ Rhabdoviruses do not encode a separate ion channel protein analogous to the M2 protein of influenza viruses. Instead, the G protein is responsible for the permeability of the envelope to protons.⁴⁹⁷ Once the M protein has dissociated from the nucleocapsid, no further uncoating is necessary, because the encapsidated RNA is the template for the viral transcriptase complex.

The first biosynthetic step in the viral replicative cycle is primary transcription, mediated by the virion-associated, RNA-dependent RNA polymerase. The mechanism of primary transcription, defined as transcription from parental templates, appears to be identical to that of secondary transcription, or transcription from progeny templates following

genome replication. The principal differences are in the much larger quantity of secondary transcripts, because of the larger number of progeny templates, and the brief time of primary transcription, compared with the prolonged period of secondary transcription throughout most of the viral infectious cycle.

The viral RNA polymerase is fully competent to synthesize all of the viral mRNA without new synthesis of viral proteins, as shown by the transcriptase activity of virion cores following solubilization of the envelope.^{51,506} Indeed, the first demonstration of a viral RNA-dependent RNA polymerase was made with virions of VSV.⁵¹ This cell-free transcriptase system has been a major tool in determining the mechanisms of viral transcription, establishing the requirement for both the L and P proteins for RNA polymerase activity²⁰³ and the requirement that the template RNA be encapsidated.^{70,202} An early insight was that a single entry point exists for the viral RNA polymerase near the 3' end of the genome, and the viral mRNAs are transcribed sequentially in the order they appear in the genome: N–P–M–G–L. Thus, transcription of each gene depends on prior transcription of all upstream genes.^{1,50,201,336,337} This has since been found to be a general property of nonsegmented, negative-strand RNA viruses (see Chapter 30).

The mechanism of sequential transcription is generally considered to be a stop–start mechanism, in which *cis*-acting signals in the template RNA sequence govern the activities of the transcriptase complex at each gene junction (Fig. 31.8). With the exception of the junction between the leader and N

FIGURE 31.8. Diagram of rhabdovirus polymerase activities during transcription in response to gene end (E), intergenic (I), and gene start (S) sequences in the genomic RNA template.

genes (discussed later), each of the VSV gene junctions contains a gene end sequence for the upstream gene (3'AUACU-UUUUUU5'); an intergenic dinucleotide (G/CA), which is not transcribed; and a gene start sequence for the downstream gene (3'UUGUC5').⁶⁰⁴ These sequences at each gene junction function as a signal for polyadenylation and termination of the upstream mRNA and also as a signal for the initiation, capping, and methylation of the downstream mRNA.^{55–57,315,630,677–679} Whereas the *cis*-acting signals in the template and the resulting modifications to the mRNA have been well defined, the mechanism by which these signals alter the activities of the transcriptase complex to accomplish these different tasks is a major question that remains to be addressed.

Transcript initiation requires both proper termination of the upstream gene and the gene start sequence 3'UUGUC5'.^{56,57,315,329,677–679} The requirements of the individual nucleotides in the start sequence for 5' end modification are more rigorous than the requirements for correct initiation.^{679,741} Alterations of the capping and methylation of the transcripts affect the processivity of the polymerase and the extent of polyadenylation of the 3' end, supporting a model in which the correct initiation and modification of the viral mRNAs play a regulatory role in the subsequent activities of the polymerase.^{255,436,741} The mechanism of 5' end modification of VSV mRNAs and likely those of other negative-strand RNA viruses differs substantially from that of host mRNAs and mRNAs of other virus types. The viral mRNAs are capped by guanosine in a 5'-5' triphosphate linkage, as are host mRNAs.² The capping reaction differs, however, in that both the α - and β -phosphates are derived from the GTP donor, whereas for host capping enzymes, only the α -phosphate is derived from the GTP donor.^{2,533} This reaction occurs through an unusual covalent L protein–RNA intermediate.⁵³³ The host translation factor EF-1 is associated with the viral L and P proteins, and it has been proposed that the α -subunit of EF-1 plays a role in the capping reaction through its guanine nucleotide-binding activity.^{124,574}

The mechanism of methylation of the viral mRNA cap is also unusual. S-adenosyl methionine is used as a methyl donor,² as with host enzymes. However, instead of having separate enzymes that catalyze ribose 2'-O methylation versus guanine-N-7 methylation, both activities appear to reside in a single domain of L.^{254,275,435,438} This domain has a single binding site for S-adenosyl methionine and transfers the methyl groups in an unconventional order, in which 2'-O methylation precedes guanine-N-7 methylation.⁵⁷⁶

Following elongation of viral mRNA, the transcriptase complex encounters a termination signal at the end of each gene consisting of the sequence 3'AUACU-UUUUUU. This signals the polymerase to "stutter" over the seven Us in the template, resulting in polyadenylation of the viral mRNA.^{55,56} Occasionally, the termination signal is ignored, resulting in read-through by the polymerase to give a dicistronic transcript.^{56,57,311} Some nonsegmented, negative-strand viruses have gene junctions with a high degree of read-through, which plays a substantial role in regulating the relative levels of the different viral proteins. Because read-through transcripts are rather uncommon for VSV, they are not thought to play a significant role in regulation of viral gene expression.

Following the polyadenylation reaction, which stops after addition of approximately 200 As, two possible fates exist for the transcriptase complex at each gene junction. The most com-

mon outcome is that the transcriptase complex traverses the two intergenic nucleotides and resumes transcription at the initiation signal of the downstream gene. Approximately 20% to 30% of transcriptase complexes fail to resume transcription of the downstream gene, however, and presumably dissociate from the template, leading to a 20% to 30% attenuation of expression of the downstream gene at each gene junction.^{336,730,757} This transcription attenuation results in a gradient of mRNA and protein expression, such that the abundance of each gene product depends on its distance from the 3' end of the genome (i.e., $N > P > M > G > L$). The G–L gene junction is unusual in that the level of attenuation is much higher than that at the other gene junctions,⁴⁹ resulting in much lower levels of L protein relative to the other viral proteins. The basis for this difference is not known, because the sequence of the G–L gene junction does not differ from that of the other gene junctions.

Transcription attenuation is a general feature of nonsegmented, negative-strand RNA viruses and is the major mechanism regulating abundance of the individual mRNA. The importance of the gene order in regulating the relative levels of viral proteins was dramatically illustrated by genetic engineering experiments to change the order of the genes of VSV. The resulting changes in relative abundance of the viral proteins resulted in substantial reductions in viral replication and pathogenesis.^{49,757} The similarity of the basic mechanisms in virus replication among nonsegmented, negative-strand RNA viruses and their dependence on the relative levels of each viral protein presumably accounts for the conservation of the basic gene order among these viruses.

The initiation and termination of transcription of the leader RNA differs from that of the viral mRNAs. The leader RNA is encoded by the 47 3'-terminal nucleotides of the genome. The leader gene differs from the other genes both in terms of the *cis*-acting signals in the template that initiate transcription⁷⁶⁰ and the nature of the product leader RNA, which is phosphorylated at the 5' end and lacks a cap structure. In addition, the sequence at the leader–N gene junction is distinct from that of the other gene junctions and lacks the U₇ sequence that governs polyadenylation.⁷⁶⁰ Correspondingly, leader RNA is not polyadenylated. Another unusual feature of transcriptional regulation at this gene junction is that its behavior is different in the cell-free transcription system versus transcription in infected cells. In the cell-free system, synthesis of leader RNA is required to transcribe the downstream N gene, consistent with the single polymerase entry site and stop–start model.^{201,762} In infected cells, however, the viral RNA polymerase can initiate synthesis at the first downstream gene without prior synthesis of leader RNA. This has been shown by inserting a small gene between the leader and N genes and determining the target size for UV inactivation of the inserted gene.⁷⁶² This is the only gene junction that shows this behavior, because transcription initiation at all of the other genes requires prior transcription of the upstream gene both in the cell-free assay and in infected cells.

The difference in the site of initiation in infected cells versus that in the cell-free system indicates that host factors can influence the site of initiation. A viral transcriptase complex has been isolated from VSV-infected cells that contains, in addition to P and L proteins, the host proteins EF-1 α , heat shock protein 60 (hsp60), and smaller amounts of the host mRNA capping enzyme guanylyl transferase.⁵⁷⁴ Unlike the virion RNA polymerase, this complex initiates transcription at

the N gene and does not transcribe leader RNA.⁵⁷⁴ The ability of the polymerase to independently initiate at the first gene downstream of the leader gene appears to account for the phenotype of a VSV mutant (polR1) that synthesizes N mRNA in excess over leader RNA,¹²⁸ which would be difficult to achieve if transcription of the N mRNA required prior transcription of the leader RNA. The mutation responsible for the polR phenotype is in the N protein associated with the template,¹²⁷ indicating that the nature of the template can influence the site of initiation.

Genome RNA Replication

Requirement for Encapsidation of Newly Synthesized RNA

A fundamental principle in replication of nonsegmented, negative-strand RNA viruses is that the ability of the RNA polymerase to replicate the viral genome depends on new viral protein synthesis to encapsidate the newly synthesized RNA. For example, treating infected cells with inhibitors of protein synthesis (e.g., cycloheximide) allows synthesis of viral mRNA but inhibits replication of genome RNA.^{324,756} The critical viral protein required for replication is the N protein, as shown by its ability to support synthesis of genome RNA in the cell-free system.⁵⁵⁰ In infected cells, however, a complex of N protein with P protein (often referred to as N_0 -P) is likely to be the active complex in promoting genome replication.^{555,556} The role of P protein in this complex appears to be to maintain the solubility and proper folding of N protein so that the nascent RNA synthesized by the RNA polymerase can be encapsidated.^{167,470,476,477} Analysis of an N_0 -P complex expressed in insect cells indicates that the complex contains one N protein and two P proteins.⁴⁸⁰

Encapsidation of nascent RNA appears to constitute a signal for the viral RNA polymerase to ignore the sequences in the genome template at each gene junction that govern the stop–start mechanism for transcription, thereby generating full-length, encapsidated RNA that is complementary to the genome (i.e., antigenomes). Use of antigenomes as templates results in synthesis of progeny genomes. The mechanism of RNA repli-

cation appears to be the same regardless of whether genomes or antigenomes are used as templates. In particular, replication of both templates requires that the nascent product RNA be encapsidated to generate full-length products. In addition to serving as a template for progeny genomes, the antigenome can be used as a template to generate a short, noncapped, nonpolyadenylated RNA complementary to the 3' end of the antigenome that is analogous to the leader RNA. Various called the *minus strand leader* or *trailer* RNA, this RNA is found in small amounts in infected cells and is the primary product produced in the cell-free system when antigenomes are used as templates in the absence of a source of new viral proteins.^{432,755,776}

Cis-Acting Signals and RNA Polymerase Complexes that Govern Replication Versus Transcription

The critical *cis*-acting RNA sequences that govern replication are located at the 3' ends of the genome and antigenome (Fig. 31.9). These sequences in the templates serve as promoters to initiate RNA synthesis, and their complementary sequences at the 5' end of the product RNA serve as encapsidation signals, with the resulting encapsidation permitting elongation of the RNA into full-length products. The sequences required for encapsidation have been mapped using synthetic RNA in cell-free encapsidation assays and also in transfected cells using minigenomes (described later).^{163,507,548,760} The sequences in the templates that serve as promoters for replication and transcription have been defined by mutagenesis studies using minigenomes.^{439,440,548,758,760} The 3' termini of the genome and antigenome of VSV are identical at 15 of 18 positions. These 18 nucleotides are essential elements of both the genomic and antigenomic promoters. The near identity of the 3' termini of the genome and antigenome implies that both RNAs display terminal complementarity. This complementarity enhances the activity of these RNA as templates for replication,⁷⁵⁸ suggesting that base pairing of the termini is an important element of promoter recognition by the VSV RNA polymerase, similar to promoter recognition by the influenza virus RNA polymerase.

The genomic and antigenomic promoters of VSV differ substantially at positions 19 to 29 and 34 to 46. These

FIGURE 31.9. Diagram of activities of the rhabdovirus genomic and antigenomic promoters in transcription versus replication.

sequences in the genomic promoter are required for mRNA synthesis, but not for replication.^{439,760} In contrast, these sequences in the antigenomic promoter serve as an enhancer of replication.⁴⁴⁰ As a result of this enhancer activity in the antigenomic promoter, replication of genomes versus antigenomes is asymmetric: many more genomes than antigenomes are synthesized in virus-infected cells.^{231,650,666,754} The functional differences between the genomic and antigenomic promoters were dramatically illustrated by engineering an *ambisense* RABV that contained the sequence of the genomic promoter at the 3' ends of both the genome and antigenome.²³¹ The promoter in the antigenome of this virus was engineered to drive the transcription of a foreign gene. As a result, both the genome and antigenome of this virus were used as templates for mRNA synthesis—the genome as a template for the five viral mRNAs and the antigenome as a template for the foreign mRNA. Furthermore, the normal asymmetry of replication was abolished, so that genomes and antigenomes were synthesized in approximately equal amounts.

In addition to differences in the *cis*-acting sequences that govern replication versus transcription, differences in the nature of the polymerase complex and the structural requirements of the P protein are also important for replication versus transcription. The C-terminal basic region of P protein that is involved in interaction with L protein is required for transcription, but not replication.¹⁶⁴ Similarly, phosphorylation of serine and threonine residues in the N-terminal domain of P protein by cellular casein kinase II is required for transcription, but not for replication.⁵⁵⁰ In contrast, phosphorylation of sites in the C-terminal domain is required for replication, but not transcription.³²⁹ These differences in the structural requirements for P protein are consistent with the idea that the polymerase complex that carries out replication is distinct from that which carries out transcription. In particular, the transcriptase appears to be an L-(P₄) complex, whereas the replicase appears to be an L-N-P₄ complex.²⁸⁶ Establishing the structural basis for the differences in replication versus transcription, particularly the ability of the two polymerase complexes to respond to *cis*-acting signals in the template and the requirement for encapsidation of the nascent product RNA, is a key issue for understanding RNA synthesis by rhabdoviruses and other nonsegmented, negative-strand viruses.

Secondary Transcription

Once nucleocapsids containing progeny genomes begin to accumulate in infected cells, they are used as templates for secondary transcription, and they are assembled into progeny virions. In the case of VSV, most of the viral nucleocapsids that are made during the infectious cycle remain associated with infected cells and are not released in the form of progeny virions,^{379,666} suggesting that use of these nucleocapsids as templates predominates over their use for virion assembly. Although conceptually it is the last step in the virus replication cycle, virus assembly begins at approximately the same time as secondary transcription (for VSV, around 2 to 3 hours postinfection), reaches a maximum rate around 8 to 10 hours postinfection when viral protein synthesis is at its maximum, and declines concomitantly with a decline in viral protein synthesis toward the end of the infectious cycle around 16 to 20 hours postinfection.

Assembly of Progeny Virions

As with most viruses, the individual components of rhabdoviruses are assembled in separate cellular compartments and only come together in the final steps of virus assembly: the nucleocapsid is assembled during the process of RNA replication as described in the previous section, the G protein is assembled in the secretory pathway, and the M protein is synthesized as a soluble protein that then associates with the cytoplasmic surface of the host plasma membrane.

Assembly of G Protein

The assembly of the VSV G protein in the secretory pathway of host cells has been studied for many years by both virologists and cell biologists, not only for its importance for virus assembly, but also as a prototype for the assembly of other host and viral integral membrane proteins. G protein is synthesized by ribosomes bound to the rough endoplasmic reticulum (ER) and is inserted into the ER membrane in the typical *type I* orientation.^{605,606} An N-terminal signal sequence of 16 amino acids targets the protein for insertion and is cleaved from the nascent polypeptide.⁴⁴⁶ The new N-terminus and most of the protein sequence (446 amino acids) are transferred to the luminal side of the ER membrane to form the protein's ectodomain.³⁶⁷ A hydrophobic sequence of 20 amino acids near the C-terminus serves as a stop-transfer sequence and becomes the membrane anchor.⁶⁰⁶ The 29 C-terminal amino acids remain on the cytoplasmic side of the ER membrane and form the protein's cytoplasmic domain.³⁶⁷ Two asparagine residues in G protein are glycosylated during translation.³⁶⁸ The initial oligosaccharides added to G protein are of the high mannose type, which are later modified by enzymes in Golgi membranes to the complex type of oligosaccharides.⁵⁸¹

Following insertion into the ER, G protein associates with two molecular chaperones, BiP (GRP78) and calnexin,^{290,467} which assist in the formation of the proper disulfide bonds and correct folding of the ectodomain. Mutations that prevent correct folding of the ectodomain or that prevent glycosylation, which is required for calnexin binding, result in the formation of aggregates of misfolded G protein together with BiP, which are not transported from the ER.^{189,467,468} Therefore, the ability of a mutant protein to be transported from the ER is a minimal criterion by which it can be said to be properly folded. Shortly after release of the properly folded G protein from the chaperones, G protein monomers associate into trimers¹⁸⁹ and are transported to Golgi membranes by membrane vesicles that bud from the ER and subsequently fuse with Golgi membranes.^{394,705} G protein is one of the most rapidly transported integral membrane proteins, requiring approximately 15 minutes to be transported from ER to Golgi membranes.⁶³ This rapid transport is dependent on a six-amino acid sequence in the cytoplasmic domain, which can function to concentrate G protein at the sites of vesicle budding.^{520,641}

Once G protein is transported to Golgi membranes, it undergoes further posttranslational modifications, including conversion of its oligosaccharides from the high-mannose type to the complex type, containing additional N-acetyl glucosamine, galactose, and sialic acid.⁵⁸¹ Although these modifications are not required for G protein function, they provide a convenient and widely used marker for transport of G protein through successive Golgi membranes.⁶³⁵ Another G protein

modification that occurs in Golgi membranes is the addition of the fatty acid palmitate to a cysteine residue in the cytoplasmic domain.^{606,625} Again, this modification does not appear to be critical, because some strains of VSV lack this modification, and mutation of the target cysteine residue, which abolishes palmitoylation, does not affect G protein function.⁷⁶⁶

Transport of G protein from Golgi membranes to the plasma membrane requires approximately 15 minutes, so that the total time from synthesis in ER to appearance in the plasma membrane is about 30 minutes.⁶³ In polarized epithelial cells, G protein is selectively transported to the basolateral surface.^{82,271,676} The same amino acid sequence in the cytoplasmic domain that promotes the rapid transport of G protein from ER to Golgi membranes is also necessary for the selective transport to the basolateral surface of polarized epithelial cells.⁷⁰³ Sorting of G protein and other basolaterally targeted proteins from those destined for the apical surface occurs first in Golgi membranes, and from Golgi membranes G protein is transported to the recycling endosome compartment prior to transport to the basolateral plasma membrane.^{20,104,155} This intermediate step presumably reflects additional sorting steps by which cells regulate the protein composition of their plasma membranes.

At the plasma membrane of infected cells, G protein is organized into clusters or *microdomains* that are approximately 100 to 150 nm in diameter.^{91,92} These G protein-containing microdomains are formed independently of other viral components⁹² and appear to be similar to cholesterol- and sphingolipid-rich *lipid rafts* that serve as sites of assembly for other viruses, such as influenza viruses.^{455,561} Lipid rafts have been defined in part by their resistance to solubilization with detergents at low temperatures.⁹⁰ In contrast to envelope glycoproteins of influenza virus and other viruses that assemble at lipid rafts, G protein in host plasma membranes and in virion envelopes is detergent soluble.⁶²² Nonetheless, the plasma membrane microdomains (and virus envelopes) that contain G protein resemble lipid rafts in that they are enriched in cholesterol and sphingolipids,^{455,561} but these lipids must not be in sufficiently high amounts to confer detergent resistance.^{93,622}

The G protein-containing microdomains at the sites of virus budding are somewhat larger (300 to 400 nm) than the microdomains in the plasma membrane outside of virus budding sites (100 to 150 nm), implying that formation of virus budding sites involves clustering of membrane microdomains.^{91,93} An interesting feature of the budding process is that envelope glycoproteins from many unrelated viruses, as well as some host integral membrane proteins, can be incorporated into the envelopes of VSV or RABV in a process referred to as *pseudotype formation* or *phenotypic mixing*. Pseudotype formation was originally demonstrated by coinfection of cells with two different viruses.⁸⁰⁷ More recently the incorporation of heterologous glycoproteins into the envelopes of VSV and RABV has been demonstrated using recombinant viruses that express the foreign glycoprotein from the viral genome.^{101,240,358,391,479,629,690} Incorporation of heterologous glycoproteins into the virus envelope appears to result from clustering of microdomains containing the heterologous glycoprotein together with G protein-containing microdomains at the sites of virus assembly.⁹³ It is not known what causes microdomains containing G protein or other glycoproteins to cluster at the sites of virus budding, but a model has been proposed in

which clustering is driven by formation of the viral nucleocapsid–M protein complex.^{93,688}

The efficiency with which heterologous glycoproteins are incorporated into the virus envelope varies over a considerable range, although thus far, none has been found to be incorporated as efficiently as G protein. In the case of RABV, interaction of the G protein cytoplasmic domain with the internal virion components may promote incorporation into the virus budding site, because appending the G protein cytoplasmic domain to foreign glycoproteins enhances their incorporation into RABV virions.^{489,490} In the case of VSV, incorporation of glycoproteins into the envelope does not depend on the sequence of the cytoplasmic domain, however, because substituting foreign sequences for the cytoplasmic domain of G protein or deleting the cytoplasmic domain does not alter the efficiency of G protein incorporation,^{92,628} and, with one exception (the human immunodeficiency virus [HIV] envelope glycoprotein),^{351,539} substituting the G protein cytoplasmic domain into foreign glycoproteins does not promote their incorporation into the virus envelope.^{358,594,629} Instead, the ability of a foreign glycoprotein to be incorporated into the VSV envelope may depend on the composition or physical properties of the microdomains containing the foreign glycoprotein. For example, the influenza virus hemagglutinin, which is in detergent-insoluble lipid rafts, is incorporated into the VSV envelope less efficiently than the T-cell antigen CD4, which is present in microdomains that are primarily detergent soluble.^{93,391,629}

The presence of G protein in the plasma membrane is not essential for virus budding, as shown by studies with recombinant VSV and RABV in which the G gene has been mutated or deleted.^{378,491,594,632,690} In the absence of a complementing source of G protein, these viruses produce noninfectious particles that lack G protein but are otherwise indistinguishable from wild-type viruses. The efficiency of virus budding, however, is reduced by at least an order of magnitude in the absence of G protein, indicating that G protein plays a role in virus assembly to enhance the budding process. Thus, not only is it likely that internal virion components promote incorporation of G protein into the envelope as described earlier, but also it appears that G protein promotes assembly of internal virion components. As with the ability to be incorporated into the envelope, the ability of the VSV G protein to promote assembly is independent of the sequence of the cytoplasmic domain, although a minimal length of eight amino acids in the cytoplasmic domain does appear to be required.⁶²⁸ Instead of the cytoplasmic domain, the sequences in G protein that are responsible for promoting assembly appear to be in the membrane-proximal amino acids of the ectodomain.⁵⁹⁴ This has led to the suggestion that these sequences are responsible for introducing curvature in the membrane that promotes budding.⁵⁹⁴ This idea is supported by the observation that G protein expressed in the absence of other viral components is released from cells in membrane vesicles that may form by a process similar to virus budding.⁵⁹⁹

Role of M Protein in Virus Assembly

Unlike G protein, the viral M protein is synthesized as a soluble protein^{379,486} and associates with membranes in the manner of peripheral membrane proteins (i.e., through a combination of ionic and hydrophobic interactions and without spanning the membrane lipid bilayer).^{430,454,455,532,797,803,804} In virus-infected

cells, most of M protein is usually localized in the cytoplasm and is found in the soluble cytosolic fraction in subcellular fractionation experiments, with smaller amounts being membrane associated.^{238,379,535,537} This distribution is also observed in transfected cells that express M protein in the absence of other VSV components,^{123,124,797} indicating that association of M protein with membranes does not depend on other viral components. In addition, membrane association does not appear to require posttranslational modification, such as phosphorylation or covalent modification with lipids.^{361,430} Instead, M protein appears to spontaneously associate with membranes containing negatively charged phospholipids,^{454,455,532,797,803} which are enriched on the cytoplasmic surface of host plasma membranes. The N-terminal 20 amino acids of M protein, which are enriched in positively charged residues, appear to be responsible for membrane association, as shown using photoactivatable membrane probes.⁴³⁰ Mutational analysis has also implicated the N-terminal region of M protein in membrane binding.^{123,160,797} The membrane-bound M protein in infected cells is organized into membrane microdomains whose size is similar to G protein microdomains.⁶⁸⁸ However, M protein and G protein reside in separate microdomains except at the sites of virus budding.⁶⁸⁸

Both the cytosolic and membrane-bound M protein are recruited into nucleocapsid–M protein complexes at the site of virus budding from host plasma membranes.^{237,528} Nucleocapsids clearly get *selected* for assembly with M protein, because most of the intracellular nucleocapsids, which are being used as templates for viral RNA synthesis, are not able to bind M protein.^{237,535,537} The only place in infected cells where co-localization of nucleocapsids and M protein is observed is in the nucleocapsid–M protein complexes in the process of budding from the plasma membrane.^{485,528,535,537} In the case of VSV, nucleocapsids containing genome RNA are incorporated into virus particles much more efficiently than those containing antigenomes.^{610,650,666,756} An RNA sequence near the 5' end of the genome has been identified that is required for nucleocapsids containing this RNA to be incorporated into virus particles.⁷⁶¹ If such a sequence is present in the RABV genome, it must also be present in the antigenome, because the recombinant ambisense RABV described earlier, which contains the genomic promoter in both the genome and antigenome, incorporates both genome and antigenome RNA into virions with equal efficiency.²³¹ One of the important questions about virus assembly that needs to be addressed is how this RNA sequence promotes incorporation into virions, because selection of nucleocapsids for virion assembly is a critical step.

Once assembly of nucleocapsid–M protein complexes has begun, the recruitment of M protein into the complex appears to occur spontaneously. This process can be recreated in a cell-free system using purified M protein and virion nucleocapsids that have been stripped of most of their M protein by treatment with high-ionic-strength buffers.^{54,461,514,515} Nucleocapsids, from which M protein has been completely removed, however, cannot rebind M protein with the same high affinity observed in virion nucleocapsid–M protein complexes.^{237,461} This suggests that addition of the initial one or a few molecules of M protein to nucleocapsids (and, therefore, their removal) is fundamentally different from that of most M protein molecules in the nucleocapsid–M protein complex. Although the basis for this difference has yet to be discovered, it is tempting

to think that it may be connected to the process of selection of intracellular nucleocapsids for virus assembly described in the previous paragraph.

Release of Assembled Virions

Following assembly of the nucleocapsid–M protein complex, the final step in virus assembly is release of the budding virion. This process is mediated by interaction of M protein with host proteins involved in MVB formation.^{298,299,331,332,345} The MVB machinery is also involved in release of retroviruses and filoviruses mediated by “late budding domains” in their Gag proteins or matrix proteins (VP40), respectively.⁵⁶⁴ In the formation of MVBs, vesicles derived from endosome membranes bud into the lumen of the endosome, carrying elements of the cytoplasm as their internal contents (Fig. 31.7). Modification of proteins on the cytoplasmic surface of the endosome membrane by covalent attachment of ubiquitin appears to be an important signal for incorporation of such *cargo* molecules into MVBs. The process of virus budding has the same membrane topology (cytoplasmic contents are internal), except that the process occurs at the plasma membrane rather than at the endosome membrane. A short sequence in M protein (PPPY in VSV, PPEY in RABV) appears to be responsible for redirecting this cellular machinery to the plasma membrane.^{298,299,331,332,345,785} No other viral components appear to be required, because expression of M protein in transfected cells in the absence of other viral components results in budding of membrane vesicles containing M protein.^{299,357,442} The PPPY sequence interacts with an E3 ubiquitin ligase called *Nedd4*, which is able to ubiquitinate M protein, in a cell-free assay.²⁹⁸ It has yet to be established whether *Nedd4* itself, or one of its numerous family members, ubiquitinate M protein in infected cells, because this is likely to involve only a small proportion of the total M protein. Nonetheless, it is likely that ubiquitination of M protein is critical for release of budding virions, because mutation of the PPPY motif in M protein, or depletion of free ubiquitin in infected cells, dramatically reduces the release of virions and causes the accumulation of budding particles at the plasma membrane because of inhibition of their release.^{298,345} One of the questions that needs to be resolved is which cellular factors involved in MVB formation are involved in virus budding? Tsg101, a protein involved in recognizing ubiquitinated cargo proteins, and Vps4a, an adenosine triphosphatase (ATPase) involved in recycling the membrane trafficking machinery, have been implicated in budding of HIV but were reported not to be involved in budding of VSV or RABV.^{331,332} However, a more recent report indicated that Vps4a is involved in VSV budding.⁶⁹⁴

MOLECULAR GENETICS OF RHABDOVIRUSES

Rapid Evolution and Existence of Quasispecies

Rhabdoviruses are classic examples of RNA viruses capable of undergoing rapid evolution. This is because of the high error rates of their RNA polymerases and their lack of proofreading activity. As a result, the rate of base substitutions during replication of genome RNA is approximately 1×10^{-4} .¹⁹⁰ Because their genomes are only slightly larger than 10^4 bases, this implies that nearly every genome contains at least one base substitution. Thus, even clonal populations of these viruses are actually collections of viruses with closely related sequences

(i.e., they are quasispecies). Because of their diversity of genome sequences, these viruses are capable of rapid genetic adaptation when placed under selective pressure of replication under different conditions. These viruses are genetically reasonably stable, however, when replication is maintained under a constant set of conditions.⁵⁹⁷ This is because the collection of genome sequences quickly reaches a consensus sequence representing the sequence with the highest level of fitness within a few replication cycles in a new host. This rapid adaptability may be advantageous in nature for viruses that alternate replication among different hosts. For example, VSV replicates both in arthropod hosts, where it establishes persistent infection, and in mammalian hosts, where it causes an acute infection. Transfer from one type of host to the other requires substantial increases in viral fitness to maintain optimal replication in the new host.⁸⁰⁶ In principle, this adaptation can occur through random mutation of the consensus sequence from the original host to one with greater fitness in the new host. However, in a virus population undergoing periodic cycling between insect and mammalian hosts, rapid adaptation to the mammalian host likely involves maintenance of a minority population of genomes in the insect host that quickly became dominant during mammalian infection.⁵²⁴ Replication of RABV is restricted to mammalian hosts, but similar though less drastic adaptation can also occur when RABV is transferred between different hosts.

The high rate of spontaneous mutation makes it feasible to isolate a variety of different types of viral mutants in the laboratory. For example, several large collections of temperature-sensitive mutants of VSV have been isolated, which fall into five or more complementation groups, corresponding to mutants with defects in each of the five viral genes.^{234,320,571} Similarly, antigenic variants that escape neutralization with monoclonal antibodies are readily isolated in the laboratory.^{410,426,459} Unlike influenza viruses and HIV, however, relatively little *antigenic drift* is found in rhabdoviruses during outbreaks in nature. This may reflect the harmful effects on G protein function of accumulating the multiple mutations necessary to escape neutralization by a polyclonal antibody response in intact animal hosts.⁵²⁵

Despite the advantages for rapid adaptation, the high rate of mutation makes these viruses susceptible to the harmful effects of *genetic bottlenecks*, in which only one or a few genomes are selected for further replication. In a process known as *Muller's ratchet*, successive passage under conditions of limited genetic diversity, such as sequential passage by isolation of individual virus plaques, leads to progressive accumulation of base substitutions, most of which decrease virus replication, thus leading to progressively lower viral fitness¹⁹² (see Chapter 11).

Defective Interfering Particles

Besides point mutations generated by nucleotide substitutions during genome replication, the other major mechanism of genetic alteration of rhabdoviruses is the generation of defective interfering (DI) particles. DI particles appear to be generated when the viral RNA polymerase switches from copying one region of the template to copying an alternate template or an alternate region of the same template. Because this inevitably results in generation of defective genomes, DI particles can replicate only in cells co-infected with standard virus to provide a source of viral proteins. If the polymerase switches to copying a distant region of the same template, this generates large

deletions of the viral genome, referred to as *internal deletion* DI particles.¹⁴⁰ In other cases, the polymerase will switch to copying the terminal sequences of the nascent product RNA strand, generating RNA products with terminal complementarity, referred to as *panhandle* or *snap-back* DI particles.⁵⁵⁷ Panhandle DI particles derived during synthesis of progeny negative-strand RNA thus have the sequence of the 5' end of the viral genome, but the 3' region of terminal complementarity has the sequence of the antigenome, including the antigenomic promoter. Because this is the more powerful of the two viral promoters, such DI genomes have a substantial replicative advantage over standard viral genomes and interfere with the replication of standard virus, resulting in reductions in virus titer.¹⁴⁰ Although they have the same genomic promoter as standard virus, internal deletion DI particles also have a replicative advantage over standard virus, presumably because of their smaller size, and they also interfere with replication of standard virus.

Defective interfering particles are readily generated during virus replication in culture, so that repeated passage at high multiplicity leads to substantial reductions in virus titer because of accumulation of DI particles.¹⁴⁰ Because of the smaller size of their genomes, virions containing DI genomes are shorter than standard virions and can be separated from standard virus by centrifugation in density gradients. This ability to physically separate virions containing DI genomes from those containing standard genomes has proved to be useful in studies of the generation and replication of DI particles. In most experimental situations, however, the presence of DI particles is more of a nuisance, so that virus stocks are usually prepared to minimize the presence of DI particles. This can be accomplished by passaging virus at low multiplicity or by plaque isolation, both of which favor the replication of standard virus over DI particles.

In principle, rhabdoviruses should be able to generate recombinants between genetically distinct viruses in co-infected cells as a result of polymerase *copy choice*, similar to the mechanisms that give rise to DI particles, in which the viral RNA polymerase switches from copying one template to copying another, leading to production of progeny genomes that are recombinants between the two parental genomes. Despite many years of the genetic study of these viruses, no convincing evidence indicates that this type of RNA recombination occurs, although the possibility of rare occurrences in nature has been proposed.¹¹⁶

Genetic Engineering of Rhabdoviruses

The methods for genetically engineering viral genomes developed with rhabdoviruses have become the standard methods used for genetic modification of many nonsegmented, negative-strand RNA viruses. A major hurdle is that RNA transcribed from complementary DNA (cDNA) needs to be encapsidated to function as a viral genome. This process, which occurs so efficiently when RNA is replicated by the viral RNA polymerase, occurs inefficiently when RNA is transcribed from cDNA. Shorter RNAs expressed from cDNA appear to be encapsidated more efficiently than longer RNA. Thus, the first viral genomes to be recovered from cDNA were a VSV DI genome⁵⁴⁹ and an RABV *minigenome* containing the terminal sequences of the viral genome required for transcription and replication flanking a foreign gene.¹⁴⁶ These genomes were expressed from plasmid cDNA in transfected cells together with plasmids encoding the N, P, and L proteins required for

encapsidation and replication. Another hurdle to the recovery of viral genomes from cDNA was the requirement for the 3' end of the RNA to reflect precisely the sequence of the viral genome (or antigenome) without additional nucleotides, in order to be recognized and replicated by the viral RNA polymerase. This was addressed by incorporating into the cDNA the sequence of the hepatitis delta virus ribozyme engineered to cleave the RNA transcript to generate a precise 3' end.⁵⁴⁹ Apparently, the sequence requirements at the 5' end of the viral RNA are not as critical, because additional nucleotides derived from cDNA are removed during replication.

The experimental approach used to generate minigenomes from cDNA led to recovery of complete viral genomes from cDNA for RABV⁶³⁴ and VSV.^{421,759} A key insight was that the RNA transcribed from cDNA needed to be the antigenome rather than the genome. Otherwise, the mRNA derived from the helper plasmids encoding N, P, and L proteins would interfere with recovery by hybridization to the genomic RNA transcribed from cDNA. In most recovery experiments, high levels of expression of the antigenome RNA and the mRNA from the helper plasmids have been achieved by infecting cells with a recombinant vaccinia virus encoding T7 RNA polymerase and transfecting them with plasmids driven by T7 promoters.^{421,634,759} Because this requires isolation of the recovered virus from contaminating vaccinia virus, methods for isolating recombinant rhabdoviruses without the use of vaccinia virus have been developed.^{297,335} Although recovery of infectious recombinant viruses from cDNA has been a major breakthrough, minigenome systems continue to be widely used for studying various aspects of the viral replicative cycle, particularly analysis of mutations that are likely to prevent replication, so that it would be difficult or impossible to isolate viruses containing such mutations.

The ability to engineer specific mutations into viral genomes has become an important tool for studying the mechanistic aspects of virus replication. In addition, it has made possible the use of rhabdoviruses as vectors for expression of foreign genes for potential use as vaccines and therapeutic agents. Several reviews have appeared on the use of rhabdoviruses as potential recombinant vaccines and as cytolytic agents for the treatment of diseases such as cancer.^{52,444,488} The basic methodology to express foreign genes is to introduce a new transcription unit containing the gene stop–start signals and the foreign gene between two of the native viral genes, such as between the G and L genes.^{492,630} The foreign gene is subject to the same transcriptional attenuation as the other viral genes. Thus, incorporation of a new gene reduces the expression of downstream genes by approximately 20% to 30%. Although this attenuation has the potential to reduce the efficiency of virus replication, incorporation of a single foreign gene usually does not notably reduce virus yields unless the foreign gene product itself has the potential to interfere with virus replication.⁶²⁹ The processes of genome encapsidation and envelopment are sufficiently flexible that incorporation of new genes into rhabdovirus genomes simply leads to longer nucleocapsids and, therefore, longer virions.⁶²⁹ In principle, no limit exists for packaging new genetic information, so that multiple foreign genes can be incorporated into genomes of recombinant viruses. Reductions in virus yield owing to multiple new transcription attenuation sites, as well as the difficulty of recovering longer genomes, however, probably places practical limits on

the amount of new genetic information that can be incorporated into rhabdovirus genomes.

MOLECULAR AND CELLULAR BASIS OF PATHOGENESIS

Induction and Suppression of Host Antiviral Responses

Two of the major determinants of viral pathogenesis are the nature of the antiviral response mounted by the infected host and the mechanisms used by viruses to suppress or evade this response. In order for cells to mount an antiviral response, viral products have to be recognized by sensors known as pathogen pattern recognition receptors (PRRs). For most cell types, the major PRR that initiates the response to many negative-strand RNA viruses appears to be a cytoplasmic RNA helicase, RIG-I (retinoic acid–inducible gene I).^{365,366} The other major PRRs that have been implicated in the host response to these viruses are Toll-like receptors (TLRs). TLRs act either at the plasma membrane or in the endocytic compartment to recognize molecules that may be associated with infection by bacteria, fungi, and protozoa as well as viruses. Activation of RIG-I or TLRs results in formation of signaling complexes through a variety of adapter proteins, which activate protein kinases that turn on the expression of antiviral genes.^{512,691} Most of the recent research in this area has focused on the production of type I (α and β) interferons (IFNs) and IFN-stimulated gene products, although other cytokines produced by virus-infected cells also play a major role in innate antiviral responses (Fig. 31.10).

One of the principal ligands for RIG-I is 5' phosphorylated RNA that is part of a short double-stranded RNA (dsRNA).^{322,623} In the normal replication cycle of nonsegmented negative-strand RNA viruses, 5' phosphorylated RNAs are produced during the process of transcription in the form of leader and trailer RNAs and during genome replication as either genomic or antigenomic RNAs (see earlier). However, the 5' ends of these RNAs are shielded by the nucleocapsid protein. Thus, removal of the nucleocapsid protein would appear to be necessary to expose free 5' ends of viral RNA and formation of dsRNA for recognition by RIG-I.⁵⁸⁴ Another potential source of such RNAs would be aberrant transcription products that are not capped by the viral polymerase. Thus, the origin of the signals that activate RIG-I is not clear, but to a large extent these signals are coupled to the production of viral RNAs.

Unlike RIG-I–dependent signaling, which is widely distributed among many cell types, the distribution of TLRs and the relative importance of their signaling pathways is often cell type dependent. For example, TLR7 is a major PRR in the response to VSV in plasmacytoid dendritic cells,⁴⁵⁸ while TLR13 and perhaps TLR4 are major PRRs in the response to VSV of splenic conventional dendritic cells and macrophages.^{266,646} The signal that activates TLR7 appears to be the presence of single-stranded RNA in the endocytic compartment.¹⁷⁶ Such single-stranded RNA can arise during virus penetration by degradation of virions or can be generated from viral RNA in the cytoplasm, which enters the endocytic compartment by autophagy.⁴²⁵ The signal that activates TLR4 in macrophages appears to be the VSV G protein, which interacts with TLR4 during virus attachment and penetration.²⁶⁶ The

FIGURE 31.10. Induction and suppression of host interferon (IFN) responses by rabies virus (RABV) and vesicular stomatitis virus (VSV). **A:** Induction of synthesis of type I (α and β) IFN and its suppression by RABV P protein and VSV M protein. **B:** Response to IFN and its suppression by RABV P protein.

signal that activates TLR13 is not known but does not appear to be related to viral RNA.⁶⁴⁶

The only TLR that has been implicated thus far in the innate response to RABV is TLR3.^{341,569} TLR3 responds to the presence of dsRNA in the endocytic compartment.¹² As pointed out earlier, dsRNAs are not part of the normal replication cycle but may arise from abnormal replication products. TLR3 may play a role in the antiviral response to RABV, but surprisingly TLR3^{-/-} mice are less susceptible to RABV than their wild-type controls.⁴⁹³ This appears to be due to a role for TLR3 in the formation of Negri bodies (described later), which are viral inclusions that may play a role in enhancing virus replication.^{411,493}

Nearly all viruses have mechanisms to evade or suppress host antiviral responses. This is a critically important aspect of viral pathogenesis. Mutations in viruses that either increase the induction or decrease the suppression of antiviral responses almost inevitably decrease virus replication in susceptible hosts. Vesiculoviruses and lyssaviruses present strikingly different approaches to this aspect of virus replication. If it is possible to generalize, vesiculoviruses usually replicate rapidly and to high levels, generating high levels of potent inducers of host antiviral responses. Correspondingly, they have rapid and potent means of inhibiting these responses, involving the general inhibition of nearly all host gene expression. In contrast, lyssaviruses do not replicate as rapidly and likely are weaker inducers of host responses. As a result, they have more subtle means of inhibiting host responses that do not involve the general inhibition of host gene expression.

Suppression of Interferon Signaling by RABV

The P protein of RABV functions both as a subunit of the viral RNA-dependent RNA polymerase and as a suppressor of IFN production and IFN signaling. P protein inhibits IFN production by preventing the phosphorylation of the transcription factor IRF-3 by two cellular protein kinases, TBK1 and IKK- ϵ (Fig. 31.10A).⁹⁷ Mutations in P protein that inactivate its IFN inhibitory function without affecting its RNA synthesis function have been identified.⁵⁸⁹ Recombinant viruses that express either mutant P protein or lower levels of P protein than their wild-type controls^{97,230} are less effective in suppressing IFN production. These viruses are able to replicate in cell types that are defective in their IFN responses but are rapidly eliminated from IFN-competent cell types and are less virulent in mice.^{97,230,589}

In addition to inhibiting IFN production, RABV P protein inhibits signal transduction in response to IFN (Fig. 31.10B). RABV P is expressed not only as full-length P protein but also as four truncated forms (P2 through P5) that are synthesized from internal start codons.⁵⁴⁶ P3, P4, and P5 proteins are found only in the nucleus. The ability of P protein and its truncated derivatives to inhibit IFN signaling is due to their ability to interfere with the transcription factors that activate interferon-stimulated genes (ISGs). Type I IFNs bind to a common receptor that is coupled to two tyrosine kinases, Jak1 and Tyk2.⁵⁷⁹ Receptor activation leads to activation of these kinases, which in turn phosphorylate two cytoplasmic proteins, STAT1 and STAT2. Phospho-STAT1 and -STAT2 are transported to the nucleus, where they associate with IRF9 to form the ISGF-3 transcription factor that activates expression of ISGs. RABV P protein does not interfere with STAT phosphorylation. Instead, it binds to phosphorylated STAT1 and STAT2 and inhibits their translocation to the nucleus and binding to target DNAs (Fig. 31.10B).^{98,119,504,728,729} This appears to be due to association of the P protein–STAT complex with microtubules in the cytoplasm, which prevents transport to the nucleus.⁵⁰⁴ STAT1–STAT2 complexes that do get transported to the nucleus associate with P protein or its truncated derivatives, which interferes with DNA-binding activity.⁷²⁹

Inhibition of Host Gene Expression by VSV

VSV inhibits host gene expression at three different levels: (a) transcription of host mRNA, (b) transport of host mRNA from the nucleus to the cytoplasm, and (c) translation of host mRNA into proteins (Fig. 31.10A). The inhibition of all three

processes presumably reflects the fact that no single inhibitory mechanism is completely effective in suppressing host antiviral responses. The inhibition of both host transcription and translation generally occurs in parallel and is usually 80% to 90% complete by 4 to 6 hours postinfection.^{7,193} Some evidence indicates that the inhibition of nuclear-cytoplasmic RNA transport may occur earlier after infection, although a direct comparison with the inhibition at other levels has not been made.^{681,732}

The VSV gene product that is primarily responsible for inhibiting host gene expression is M protein. Expression of VSV M protein in transfected cells in the absence of other viral components inhibits expression of co-transfected genes driven by a wide variety of different promoters.^{4,72,225,462,541} This inhibitory activity of M protein is very potent and is evident even when M protein is expressed at 100 to 1,000 times lower levels than those in VSV-infected cells.⁴⁶² Viruses containing a variety of M protein mutations are defective in their ability to inhibit host gene expression.^{5,7,73,151,175,225,245,346,681} Most of these mutations that render M protein defective in its ability to inhibit host gene expression do not affect its functions in virus assembly. Conversely, M protein mutations such as truncation of the N-terminal sequences that are important for virus assembly do not affect the ability of M protein to inhibit host gene expression.^{73,346} Thus, the functions of M protein in the inhibition of host gene expression are genetically separable from its virus assembly functions. Although no separate M protein domains appear to mediate these two classes of functions, the point mutations that affect inhibition of host gene expression do map to one face of the M protein three-dimensional structure. Presumably, this face of M protein is involved in interaction with host components involved in the inhibition.

Because M protein lacks any enzymatic activity, it probably interferes with host gene expression by interacting with cellular proteins to alter their function. Thus far, the only host protein whose binding to M protein is correlated with the inhibition of host gene expression is Rae1.²¹³ Rae1 was originally implicated in mRNA transport, but more recent experiments suggest its principal function is in mitotic spindle assembly and mitotic checkpoint regulation.^{30,79,651,787} M protein and Rae1 form complexes with multiple proteins involved in mRNA transport and other cellular functions, such as Nup98, hnRNP-U, and E1B-AP5.^{115,213,732} However, deleting the *Rae1* gene in cultured mouse embryo cells or silencing its expression in *Drosophila* does not lead to mRNA transport inhibition.^{30,651} Given the observation that Rae1 is not essential for nuclear-cytoplasmic RNA transport, it is unlikely that the VSV M protein inhibits host gene expression simply by interfering with Rae1 function. Instead, it is more likely that the complex of M protein and Rae1 interferes with the function of other factors that are essential for host gene expression.

Because Rae1 is distributed throughout the cytoplasm and the nucleus of the cell, M protein-Rae1 complexes may be involved in inhibition of multiple steps in host gene expression. In support of this idea, the inhibition of transcription by host RNA polymerase II involves inactivation of the general transcription factor TFIID,⁸⁰⁰ which binds to the TATA box upstream of most RNA polymerase II-dependent promoters and recruits other general transcription factors to these promoters. M protein, however, does not appear to interact directly with TFIID,⁷⁹⁹ suggesting that the inactivation is indi-

rect. The mechanisms involved in such an indirect effect have yet to be discovered.

The inhibition of host translation in VSV-infected cells does not result from depletion of cellular mRNA secondary to the inhibition of mRNA transcription and transport. As described earlier, the inhibition of host translation occurs early in the infectious cycle on a time scale too rapid to be caused by turnover of cellular mRNA. Instead, the translation apparatus is reprogrammed such that only new mRNAs are translated.⁷⁶³ Pre-existing host mRNAs are incorporated into translationally inactive messenger ribonucleoproteins (mRNPs), where they are stably maintained in infected cells.^{608,764} Thus, the inhibition of host translation reflects the inhibition of translation of pre-existing mRNAs together with the lack of production of new host mRNAs due to the inhibition of transcription and transport by M protein. The reprogramming of the translation apparatus appears to be due at least in part to alterations in the cap-binding translation factor eIF4F.^{142,143,191} How the changes in the eIF4F complex result in the altered translation in VSV-infected cells is a major question that remains to be addressed.

Viral transcription provides a continuous supply of newly synthesized viral mRNAs, which are efficiently translated by the reprogrammed translation apparatus. Translation of viral mRNAs continues until late in the infectious cycle, when translation is inhibited because of phosphorylation of eIF2 α by the antiviral kinase PKR, as well as other mechanisms.^{142,143,764} Viral mRNAs do not appear to have *cis*-acting sequences that promote their translation analogous to the internal ribosome entry sites in picornavirus mRNAs.⁷⁶⁴ Regardless of their sequences, new mRNAs are translated more efficiently in VSV-infected cells than in uninfected cells.⁷⁶³ This enhancement of translation of new mRNAs appears to involve M protein, because M protein mutant viruses have been identified that inhibit host translation as effectively as their wild-type controls but are defective in promoting translation of viral mRNAs.^{144,499}

Induction of Cytopathic Effects

As in the case of suppression of host antiviral responses, lyssaviruses and vesiculoviruses present strikingly different abilities to induce cytopathic effects in infected cells. In the case of most RABV strains, usually few, if any, morphologic changes occur in infected cells that would be interpreted as cytopathic effects until several days after infection. Indeed, some cell types infected with RABV continue to divide and establish persistent infections.²²³ In contrast, many strains of VSV are among the most cytotoxic of animal viruses, at least in mammalian and avian cells. In many insect cells, however, VSV replication is attenuated and a persistent infection is established with little, if any, cytopathic effect.⁷⁹⁴ In most cases, cytopathic effects are a result of host responses to virus infection involving activation of programmed cell death or apoptosis.

Induction of Apoptosis by Vesicular Stomatitis Virus

It is widely appreciated that many viruses induce apoptosis in infected cells, and, in general, apoptosis is a form of antiviral response in which death of the host cell should reduce the number of progeny resulting from the infectious cycle. VSV was one of the early viruses shown to induce apoptosis in infected cells.³⁸⁹ In fact, most, if not all, of the cytopathic effects of VSV infection are caused by the induction of apoptosis. These effects include nearly all of the morphologic and biochemical

changes typical of apoptosis in cell culture.^{384,389} One of the earliest effects is cell rounding, followed by membrane blebbing, nuclear condensation and DNA fragmentation, cytoplasmic shrinkage, and cell lysis. Despite the general opinion that apoptosis of infected cells reduces virus yield, little, if any, difference exists in yield of VSV if apoptosis is delayed by overexpression of the antiapoptotic host protein Bcl-2,³⁸³ indicating that the VSV replication cycle is largely complete before the infected cell has a chance to die.

At least two distinct mechanisms exist by which VSV infection can induce apoptosis in infected cells.^{109,253,384,553} One appears to be a direct result of the inhibition of host gene expression by M protein, and thus is only activated by viruses with wild-type M protein. The other mechanism appears to be a cellular response to virus replication and is induced by both wild-type and M protein mutant viruses. The relative importance of these two mechanisms varies widely among different cell types, depending on the nature of the proteins that regulate apoptosis pre-existing in the cell before infection and the contribution of newly synthesized proapoptotic protein induced after infection.^{109,252,253,383,553,616} Such newly synthesized proapoptotic proteins can contribute to apoptosis induced by M protein mutant viruses but are suppressed by viruses with wild-type M protein.

Wild-type M protein induces apoptosis when expressed in transfected cells in the absence of other viral components.³⁸⁴ In contrast, mutant M proteins that are defective in their ability to inhibit host gene expression cannot induce apoptosis in the absence of other viral components.^{383,384} Induction of apoptosis by M protein appears to be similar to that induced by pharmacologic inhibitors of host gene expression (e.g., actinomycin D). As with most forms of intracellular damage, both M protein and pharmacologic inhibitors of host RNA synthesis activate the *mitochondrial pathway*, involving the release of cytochrome c and other proapoptotic proteins from mitochondria, which activate the upstream caspase, caspase-9.^{48,383} As a result, induction of apoptosis by M protein can be inhibited by overexpression of antiapoptotic proteins like Bcl-2 and Bcl-X_L, which prevent release of proapoptotic factors from mitochondria.

Despite the inability of mutant M proteins to induce apoptosis in the absence of other viral components, M protein mutant viruses, which are defective in their ability to inhibit host gene expression, are still very effective inducers of apoptosis in infected cells.^{109,252,253,383,384,644} The induction of apoptosis by M protein mutant viruses appears to be part of the antiviral response induced by virus replication. In contrast to apoptosis induced by M protein alone, the death receptor pathway is the major mechanism of cell death, in which caspase-8 is the major upstream caspase, rather than caspase-9.^{109,252} The Fas death receptor appears to be the major death receptor involved. In contrast to viruses such as influenza virus, in which Fas signaling is mediated through the adaptor protein FADD,⁴⁸ VSV infection appears to activate an alternative adapter protein Daxx, which is involved in the induction of apoptosis.²⁵² In some cell types, cross-talk between the death receptor and mitochondrial apoptotic pathways is required for efficient induction of cell death. This cross-talk is mediated through caspase-8 cleavage of the pro-apoptotic BH3-only protein Bid. Cleaved Bid (tBid) then promotes destabilization of the mitochondria through activation of pro-apoptotic mitochondrial proteins. Death receptor signaling has been classified as type I

or type II depending on whether signaling is independent of the mitochondrial pathway (type I) or depends on amplification by the mitochondrial pathway (type II).^{619,620} Cells that respond to death receptor ligands by a type II pathway also respond to VSV infection by a similar pathway.¹⁰⁹

Induction of Apoptosis by Lyssaviruses

As pointed out earlier, there are cell types in which RABV induces little, if any, cytopathic effect and establishes persistent infections.²²³ In other cell types, the infected cells eventually die as a result of induction of apoptosis.^{340,718} Furthermore, RABV induces apoptosis in infected neurons *in vivo* during experimentally induced encephalitis in mice.³⁴⁰ Inhibition of host gene expression does not play a role in the induction of apoptosis by RABV as it does in the case of VSV. Indeed, RABV infection induces the expression of host pro-apoptotic proteins, such as Bax,⁷¹⁸ and in this regard, resembles the induction of apoptosis by M protein mutants of VSV that do not inhibit host gene expression. Also analogous to VSV M protein mutants, the induction of apoptosis depends on activation of the death receptor pathway involving caspase-8, in the case of two other lyssaviruses, MOKV and LBV.³⁶⁴ In contrast to the activation of the Fas death receptor by VSV M protein mutants, however, MOKV and LBV activate apoptosis through interaction of the death ligand tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) with its receptor.³⁶⁴ Transfection of cells with plasmids encoding lyssavirus M proteins induced apoptosis by the same caspase-8-dependent and TRAIL-dependent mechanism and also through mitochondrial disruption.^{269,364} It is unlikely, however, that the lyssavirus M proteins induce apoptosis by a mechanism similar to VSV M protein, because they do not inhibit host gene expression. In addition to M protein, G proteins of some RABV strains also induce apoptosis.^{568,570} Thus, it is likely that multiple viral components are involved in the induction of apoptosis in cells infected with lyssaviruses.

MOUSE MODELS OF RHABDOVIRUS INFECTION

Both RABV and VSV are highly neurotropic in mice, and virulence is largely due to virus-induced encephalomyelitis. Laboratory rodents (e.g., mice) have been extensively used for rabies diagnosis, vaccine potency testing, and pathogenic studies, although these taxa are epidemiologically insignificant as lyssavirus vectors or reservoirs,^{121,396} compared with the families *Carnivora* and *Chiroptera*. Similarly, rodents are not known to be natural hosts for vesiculoviruses. In fact, the disease induced by VSV in rodents bears little resemblance to the disease in natural hosts, such as horses and cattle (described later). Nonetheless, much of what we know about the mechanisms of pathogenesis and immunity for these viruses is derived from experimental infection of mice.

Entry and Site of Initial Replication

Infection of mice with RABV is usually fatal regardless of the route of inoculation. Intramuscular inoculation is often used as a model for virus transmission by animal bites, and intranasal inoculation is used as a model for the occasional transmission

of RABV by inhalation. In contrast to RABV, the ability of VSV to invade the CNS is highly dependent on the age of the mice and route of inoculation,⁶¹⁵ as well as the strain of mice infected.^{196,244} In general, adult mice are relatively resistant to VSV inoculated intravenously or intraperitoneally, although systemic virus infection clearly occurs in these mice, as shown by the potent induction of immune responses (described later). In contrast to intravenous or intraperitoneal inoculation, mice are very sensitive to VSV introduced by intranasal or intracerebral inoculation. As an example of strain differences, mice of the 129 strain, which are often used in the generation of transgenic mice, were found to be five orders of magnitude more resistant than strains such as BALB/c, which are often used in studies of immunology and pathogenesis.¹⁹⁶

Virus entry into the host is accompanied by initial virus replication at the site of entry. In the case of RABV infection of mice, initial replication following intramuscular inoculation can occur in either sensory or motor neurons without apparent replication in muscle,^{150,642} although in natural hosts, virus can replicate in muscle tissue before progressing to the peripheral nervous tissue via neuromuscular connections.^{117,219,511} In the case of either RABV or VSV infection following intranasal inoculation (Fig. 31.11), the primary site of virus replication is in olfactory receptor neurons and other cells of the olfactory epithelium.^{409,563} In addition to olfactory epithelium, VSV can also infect cells of the respiratory epithelium and spread through the respiratory tract to the lungs, although little, if any, pathology is associated with virus replication in the lungs.²⁴⁴

Virus Spread and Tissue Tropism

Both RABV and VSV are transmitted to the CNS primarily by neural spread along the tracts served by the initially infected neurons. For example, following intramuscular inoculation,

RABV spreads from the initially infected sensory and motor neurons to the spinal cord and sensory ganglia in subsequent rounds of replication.¹⁵⁰ Similarly, following intranasal inoculation (Fig. 31.11), both VSV and RABV quickly spread to the glomerular cells of the olfactory bulb as well as the anterior olfactory nuclei.^{327,409} From these sites, the viruses spread to other parts of the CNS that are served by the neurons that innervate the olfactory bulb. These viruses have a clear preference for some classes of neurons over others. For example, RABV can also enter the CNS through neurons of the trigeminal ganglia,^{409,642} whereas VSV cannot.⁵⁶³ Similarly, RABV infects mitral cells of the olfactory bulb and spreads along tracts served by these cells,⁴⁰⁹ whereas VSV does not.³²⁷ In addition to neural spread, VSV infects cells lining the ventricular system, where it can be released into the cerebrospinal fluid (CSF) and can spread to other parts of the brain and spinal cord, leading to paralysis.^{244,327,563}

The pathology associated with infection of mice by either RABV or VSV is typical of viral encephalomyelitis, involving both death of infected cells and inflammation at the infection sites. The inflammatory changes include activation of resident inflammatory cells (e.g., microglia) and infiltration of inflammatory cells (e.g., monocytes, natural killer [NK] cells, and T cells).^{67,126,244,321} The morbidity and mortality associated with virus infection is usually attributed to virus-induced death of infected cells that are critical for the host, rather than to immunopathologic mechanisms, because nearly all experimental manipulations that reduce the immune response to virus infection either enhance mortality by allowing more virus replication or have little effect. For example, virus infection of T-cell-deficient mice results in more extensive spread of virus throughout the brain and higher mortality than in immunocompetent mice.^{321,326}

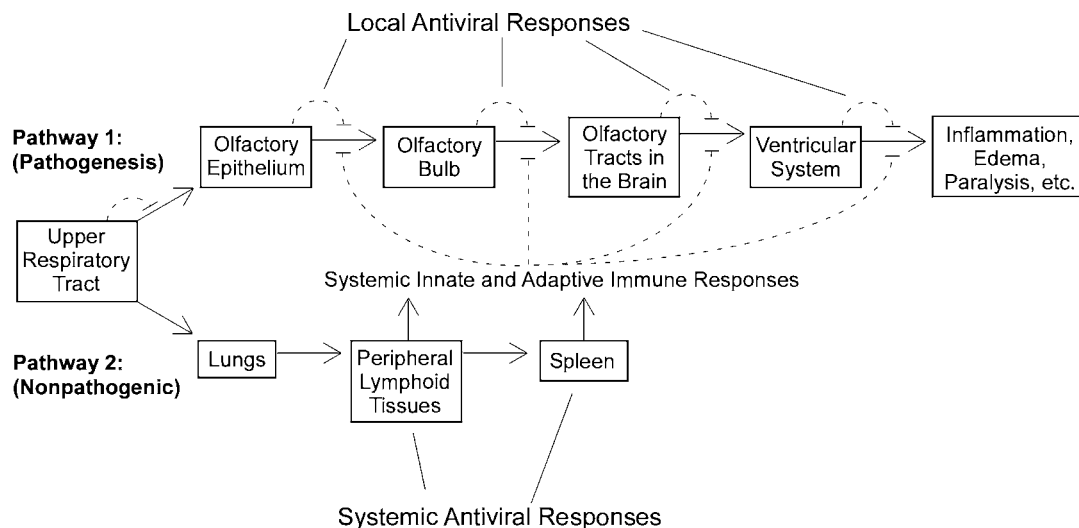

FIGURE 31.11. Diagram of pathogenesis and immune response in mice infected with vesicular stomatitis virus (VSV) by intranasal inoculation. Pathway 1 is the route of virus spread through the central nervous system by neuronal transmission leading to encephalitis.³²⁷ **Pathway 2** is a hypothetical route of spread from the respiratory tract to peripheral and central lymphoid organs. Also shown are sites at which local and systemic antiviral responses exert an inhibitory effect on spread of virus to the next stage. The outcome of infection depends on the relative ability of the virus to replicate and spread versus the ability of the host to inhibit virus replication at each step.

Immune Responses Involved in Recovery from Rhabdovirus Infection

The immune response to VSV infection in mice has been studied for many years by viral immunologists as a prototype immune response to virus infection. In addition, the development of recombinant VSV as a potential vaccine vector⁵⁹² has stimulated additional research into the anti-VSV immune response. In most cases, the infection resulting from intraperitoneal or intravenous inoculation has been studied, which often is asymptomatic and results in complete recovery in immunocompetent mice. Less frequently studied is the infection resulting from intranasal inoculation. In this case, nearly all mice develop clinical signs, and only about half of the mice survive. Clearly, differences in the immune responses resulting in resistance or recovery must exist between these two situations. In the case of RABV, there is little incidence of recovery from a productive CNS infection. The immune response to attenuated virus strains is often studied as a model for the immune response to potential live virus vaccine strains.

Immune Response to Vesiculovirus Infection

In the case of VSV infection, elements of both the innate and adaptive immune response are critical for survival (Fig. 31.11). One of the most striking effects on VSV pathogenesis occurs in the absence of a response to type I (α and β) IFN. Mice that lack the type I IFN receptor, or the STAT1 transcription factor that mediates many of the effects of type I IFN, are extremely susceptible to the lethal effects of VSV infection.^{195,510} In contrast to immunocompetent mice, in which virus replication occurs primarily in the CNS, in IFN receptor- or STAT1-deficient mice VSV replicates to high titer in all of the tissues tested.^{195,510} In fact, the brains of these mice had the lowest titers of any of the organs examined.⁵¹⁰ This result implies that the pronounced neurotropism of VSV in immunocompetent mice is not caused by the inherent ability of different tissues to support virus replication, but rather differences in their ability to produce or respond to type I IFN.

As in the case of most viruses, no single IFN-inducible gene product is responsible for the effect of IFN in protecting nonneural tissues from VSV infection. No deletion of a single IFN-inducible gene has as profound an effect as deficiency of IFN receptor or STAT1. The antiviral protein kinase PKR is notable, however, in that its deletion leads to enhanced virus replication in the lung following intranasal inoculation, leading to enhanced morbidity and mortality caused by respiratory infection.¹⁹⁶

The major source of type I IFN in mice following systemic inoculation appears to be a subclass of plasmacytoid dendritic cells residing in the marginal zone of the spleen.⁵³ This would be consistent with the ability of VSV to suppress IFN production by most other cell types, as described in the previous section. Dendritic cells containing TLR7, such as plasmacytoid dendritic cells, appear to be resistant to the inhibition of IFN production following VSV infection.^{8,458,734} Other cell types involved in innate immunity also appear to be involved in protecting neural and nonneural tissues from VSV infection. Following systemic inoculation, chemokine-secreting marginal zone macrophages in the spleen are particularly important,^{132,529} and following subcutaneous inoculation, subcapsular macrophages in draining lymph nodes are critical

for preventing VSV neuroinvasion through peripheral nerves in the lymph nodes.³³⁰

Whereas the host IFN response and other innate immune mechanisms can protect most nonneural tissues from VSV infection, they do not fully protect the CNS, particularly following intranasal or intracerebral inoculation. This inability to protect the CNS is not because of a failure of neurons to respond to IFN.⁷¹⁰ Instead, the problem appears to reside in the amount of IFN produced in the CNS and the timing of the peripheral IFN response relative to virus invasion.⁷¹¹ Indeed, treating mice with exogenous IFN can increase their resistance to CNS infection by VSV.^{168,281,708} In addition to the IFN response, other innate immune mechanisms affect the susceptibility of the CNS to VSV infection. For example, deficiency in the production of nitric oxide by neuronal nitric oxide synthase-1 (NOS-1) enhances the susceptibility of the CNS to infection.³⁸² In contrast, deficiency of the inducible NOS (NOS-2) or NOS-3 has little effect on VSV infection of the CNS.

In addition to innate immune responses, adaptive immune responses are critical for recovery from VSV infection. Particularly important is the production of neutralizing antibodies. As with most viruses, the envelope glycoprotein of VSV (G protein) is the viral antigen that elicits neutralizing antibodies.^{108,359,427} Induction of antibodies by G protein expressed on the surface of infected cells requires T cells.³¹ The high density of G protein in virions is able to induce a T-cell-independent IgM response, however, which is consistent with the induction of T-cell-independent responses by antigens with highly repetitive epitopes.³¹ T cells are required for isotype switching to produce immunoglobulin G (IgG) and other isotypes.^{428,471} VSV-infected dendritic cells appear to be responsible for transporting the virus to secondary lymphoid organs, such as the spleen (Fig. 31.11), where they present viral antigens to virus-specific T cells and B cells.^{131,132,456} The CD4+ T-helper cell (Th) response to VSV infection includes elicitation of both Th1 and Th2 cells. The response is predominantly of the Th1 type, resulting in secretion of IFN- γ and isotype switching in B cells to produce predominantly IgG2a antibodies. Isotype switching to IgG2a is also mediated by IFN- γ -producing γ - Δ T cells.⁴⁷¹ This polarization of the T-cell response presumably reflects secretion of IL-12 by dendritic cells and other antigen-presenting cells. Depletion of phagocytic cells, including marginal zone dendritic cells and macrophages, largely eliminates the Th1 response, although the Th2 response is left largely intact, suggesting that a different class of antigen-presenting cells is responsible for activation of Th2 cells.¹³²

VSV infection also effectively elicits CD8+ cytolytic T cells (Tc). In contrast to neutralizing antibodies, which are serotype specific, many of the Tc cells are cross-reactive between Indiana and New Jersey serotypes of VSV.⁶⁰⁹ These cells recognize peptides containing conserved sequences derived from G protein or N protein (and perhaps other viral proteins) presented in the context of class I major histocompatibility complex (MHC) molecules on virus-infected cells.^{572,722,798} In addition to CD8+ Tc, VSV also elicits CD4+ cytotoxic T cells, which recognize epitopes derived from G protein presented in the context of class II MHC molecules.⁹⁴

The importance of the antibody response in recovery from VSV infection is demonstrated by the observation that mice containing disruptions of the immunoglobulin μ gene are highly susceptible to VSV infection.⁹⁵ These mice die

from CNS infection, even when infected by intraperitoneal inoculation. In contrast, depletion of either CD4+ or CD8+ T cells has little effect on susceptibility to VSV infection by this route.⁴²⁸ Depletion of either T-cell subset or both subsets, however, enhances the susceptibility of mice to infection with VSV by intranasal inoculation,³²⁶ indicating that T cells are important for reducing virus replication once infection is established in the CNS.

Immune Response to Lyssavirus Infection

Antibodies induced by vaccination, particularly those with neutralizing activity, play a prominent role in immune defense against RABV infection.³²¹ On rare occasions, immunity can also be naturally acquired after multiple exposures to virus.²⁴² The G protein represents the only antigen that induces neutralizing antibodies and is able to confer immunity against a lethal challenge.¹⁵³ Antibodies can mediate viral clearance from the CNS without other immune effectors.¹⁸⁰ The presence of other immune mechanisms, including IFN responses, and both CD4+ and CD8+ T cell responses, however, hastens the clearance of virus from the CNS.³²¹ Although G protein is the only antigen that elicits neutralizing antibodies, the RNP is a major antigenic complex that induces a virus-specific antibody response, and antibodies directed against RNP can contribute to protection against infection.^{179,182,448} Animals treated with anti-N sera can be protected against a subsequent challenge with RABV, and anti-N sera can exhibit an antiviral activity *in vitro*.⁴⁴⁸ The mechanism by which anti-RNP antibodies inhibit viral replication, however, remains unclear.

Infection with RABV results in the generation of virus-specific CD8+ and CD4+ T cells. The G protein is one of the antigens that induces Tc responses.^{465,466} Some mouse strains infected with virus also develop strong Tc responses to the P protein.⁴¹⁷ The role of CD8+ T cells in immune defense is unclear, however. Some investigators report clearance of rabies virus after transfer of RABV-specific T cells and protection against rabies by a Tc clone, whereas other investigators showed that Tc are insufficient to protect against challenge, and *in vivo* depletion of CD8+ T cells had no effect on host resistance to street virus infection.^{369,417,558,566} In contrast, Tc may actually be involved in the immunopathology and have been implicated in neuritic paralysis.^{683,752} By comparison, the induction of CD4+ T cells is an integral part of the protective immune response against rabies.¹⁷⁸ Elimination of CD4+ cells abrogates the production of IgG neutralizing antibody in response to virus infection.⁵⁵⁸ The RNP contains major epitopes that induce CD4+ T-cell responses, and most of these T cells cross-react with other lyssaviruses.²⁰⁷ The RNP-specific T cells, which can augment the production of neutralizing antibody, are believed to be the major factor that mediates the protective immune response induced by internal viral antigens.^{181,251}

Determinants of Viral Virulence

In general, determinants of viral virulence among rhabdoviruses can be classified into those that enhance virus replication and those that enhance the suppression or evasion of host antiviral responses. Mutations in such virulence determinants are of considerable interest, because of their potential to generate live virus vaccines. In the case of RABV, much attention has focused on mutations in G protein that attenuate viral pathogenicity. For example, antigenic variants selected with neutralizing

monoclonal antibodies against G protein often display reduced neurovirulence in mice. These variants contain mutations that change R/K333 in G protein to other amino acids. These changes reduce the ability of G protein to attach to neuron-specific receptors,^{152,713} although virus replication in nonneuronal cells is not affected. Similarly, mutations in VSV that compromise its ability to replicate often result in attenuated virus strains. For example, truncation of the G protein cytoplasmic domain reduces the efficiency of virus budding, as described earlier. Such mutants are attenuated in their pathogenicity and form the basis for candidate recombinant viral vaccines.^{592,607} Likewise, recombinant viruses in which the order of the VSV genes has been altered usually display reduced pathogenicity as a result of reduced virus replication and are candidate recombinant vaccines.^{147,236}

An example of the second class of virulence determinants—those that lead to suppression of host antiviral responses—would be the VSV M protein. Mutations in M protein that render it defective in its ability to inhibit host gene expression attenuate viral virulence in mice without compromising the ability of the virus to replicate in cell culture.^{3,6,681} In this case, the attenuation is caused by the enhanced innate immune responses elicited in infected cells because of the failure of the virus to suppress host gene expression.⁷¹¹

Similar to VSV M protein mutants, RABV P protein mutants have been generated that are defective in their ability to block IRF-3 phosphorylation⁵⁸⁹ or STAT1 nuclear translocation.³³⁴ These viruses are also attenuated in their pathogenicity in mice, emphasizing the importance of P protein-mediated suppression of IFN responses as a virulence factor for RABV. However, equally important virulence factors for RABV are viral mechanisms that suppress production of the activators of innate antiviral responses. The difference in pathogenicity of attenuated viruses compared to field strains (i.e., street viruses) is correlated with lower levels of viral gene expression by the more virulent strains.^{502,743} This leads to correspondingly lower induction of antiviral responses by the more virulent viruses. Similarly, strain differences in the N protein have been linked to differences in RIG-I signaling and corresponding differences in virulence.⁴⁷⁵ Thus, the key to the pathogenicity of RABV is the combination of having a potent suppressive mechanism to inhibit IFN responses in susceptible cells together with a sufficiently low level of viral gene expression to reduce the responses generated in the cells of the innate immune system. In other words, RABV is said to “[use] stealth to reach the brain”.⁶³³

EPIDEMIOLOGY OF RHABDOVIRUS INFECTIONS

Epidemiology of Lyssavirus Infections

Lyssavirus epidemiology is partially influenced by host species distribution, abundance, demographics, behavioral ecology, dispersal, and interactions with humans.⁶¹⁴ Because of its consequences when ignored, rabies is a reportable disease in many countries, although surveillance is inadequate, particularly in sylvatic hosts. Biased epidemiologic information usually derives from clinical reports or the examination of suitable brain material submitted to public health or veterinary diagnostic laboratories only after infectious contact with animals is suspected.

Exposure is generally defined as transdermal contact, typically by a bite, or mucosal contamination with potentially infectious material (e.g., saliva or CNS tissue).⁷⁸⁹ The relative risk associated with other scenarios is difficult to define.

The domestic dog is the principal host and major vector of rabies throughout the world,^{217,740} currently most prominent in the tropical regions of Asia, Latin America, and Africa. International reporting of both human and animal rabies cases grossly underestimates the magnitude of the problem.⁴⁹⁵ Predominant wild reservoirs and maintenance hosts belong to the family *Carnivora*^{38,376} and include foxes^{74,154} in the Arctic (*Vulpes lagopus*), Canada, central and western Europe, and moderate latitudes of Asia (*V. vulpes*, *V. corsac*), and scattered foci elsewhere throughout North America (e.g., *Urocyon cinereoargenteus*); the raccoon dog (*Nyctereutes procyonoides*) in eastern Europe, Scandinavia, and portions of Asia^{120,395,526}; coyotes, jackals (*Canis* species), and other wild canids in North America, Asia, and Africa²⁵⁸; skunks (*Mephitis mephitis*, *Spilogale putorius*) in North America^{118,280}; procyonids, such as the raccoon (*Procyon lotor*), in eastern North America^{68,778}; and herpestids (e.g., the yellow mongoose, *Cynictis penicillata*; the small Asian mongoose, *Herpestes javanicus*) and their relatives throughout Africa, Asia, and the Middle East.⁷²⁵ Additionally, the ferret badger (*Melogale moschata*) was documented as a rabies reservoir in several regions of China.^{447,809} Rabies detection in rodents is uniformly rare.^{121,396,779}

Bat rabies predominates in the New World, described primarily among insectivorous bats of the United States and Canada (over 40 species) and the three hematophagous vampire species (principally, *Desmodus rotundus*) ranging from northern Mexico to Argentina.^{39,122} Many bat species may also be important throughout Latin America.^{169,170} Other lyssaviruses are transmitted by bats in Africa, Europe, Asia, and Australia.^{17,42,247,400,402,403}

Surveillance efforts in the United States follow changes in indigenous and translocated cases in space and over time. For example, in 2009, 49 states and Puerto Rico reported 6,690 rabid animals and 4 human rabies cases to the Centers for Disease Control and Prevention (CDC). Approximately 92% of reported rabid animals were wildlife. Relative contributions by the major animal groups were 34.8% raccoons, 24.3% bats, 24.0% skunks, 7.5% foxes, 4.5% cats, 1.2% dogs, and 1.1% cattle. Compared with 2008, reported numbers of rabid raccoons and bats decreased, whereas reported numbers of rabid skunks, foxes, cats, cattle, dogs, and horses increased.⁷⁵ Historically, Hawaii remained the only rabies-free state, never having reported a case of indigenously acquired rabies.^{233,618}

Combined with historical, temporal, and spatial disease surveillance data, antigenic characterization with monoclonal antibodies (MAbs) and nucleotide sequence analysis can assist in the assignment of isolates to different animal reservoirs.^{661,663,664} Arctic RABV circulates circumpolarly, although local variability was documented in several areas, such as Alaska and Ontario. Although *V. lagopus* historically has been recognized as the major reservoir of Arctic RABV, *V. vulpes* increasingly participates in circulation of this virus variant due to climate changes. Skunk rabies isolates appear to be distinct variants defining separate outbreaks in the north-central and south-central parts of North America, and California. Additionally, smaller independent foci involve foxes, dogs, and coyotes in Texas, as well as foxes in Arizona and portions of the southwestern United States.^{75,135,390,660,661,663}

Analysis of human rabies cases from the United States implicated viruses associated with insectivorous bats as the most frequent source of infection after elimination of canine rabies,^{75,390,522} and some bat isolates appear to possess unique pathogenic properties compared with isolates from the family *Carnivora*.⁵⁰⁵ During 2003, a first reported occurrence of rabies in a human infected with the raccoon rabies virus variant was documented in Virginia; however, the exposure history was unknown. During 2004, transplantation from an infected donor resulted in four human cases in the United States⁶⁶⁹ and three in Germany,³⁰⁶ demonstrating the devastating consequences when rabies is not suspected.

Host switching from bats to terrestrial mammals during the history of lyssavirus evolution has been inferred from RABV phylogeny.³⁵ Based on the relatedness of carnivore RABV variants to bat RABV variants, the switch is proposed to have occurred approximately 1,000 to 1,500 years ago. Moreover, relatively frequent spill-over cases and host shifts of bat RABV variants to terrestrial mammals have been documented repeatedly during recent years.^{23,433} More controversial is a proposed cross-species shift in lyssaviruses, given that a variety of non-RABV lyssaviruses, but not RABV, have been detected in bats in the Eastern Hemisphere, and only RABV detected in all reservoir hosts, including bats, in the Western Hemisphere.⁴⁰⁶

In western and central Europe, where fox rabies has been largely eliminated via oral vaccination, bat rabies still poses public health concerns. The EBLV-1, first isolated in 1954 in Germany, was later identified across Europe, from Spain to the Ukraine.^{17,401} About 95% of EBLV-1 cases have been observed in *E. serotinus* bats.^{17,627} However, it has also been reported in numerous other bat species.^{627,637,638} Spill-over infections of EBLV-1 were documented in sheep in Denmark,⁶⁰⁰ in stone marten in Germany,⁵⁰⁹ and in domestic cats in France.¹⁵⁹ In contrast to EBLV-1, distribution of EBLV-2 is limited to northwestern Europe.⁴⁰⁶ This virus circulates primarily among bats of the *Myotis* genus. Five human rabies cases of bat origin have been documented in Europe. In one case the virus was identified as EBLV-1, in two others EBLV-2 was identified, and in two cases the virus was not characterized.⁴⁰⁶

Bat lyssavirus surveillance in southeastern Europe and Asia is extremely limited. Nevertheless, such viruses as ARAV and KHUV were isolated from *Myotis* bats in Central Asia,⁴⁰⁵ IRKV was isolated from *Murina leucogaster* in Eastern Siberia⁸¹ and later caused a human rabies case in the Far East,⁶² and WCBV was isolated in the Caucasus region from *Miniopterus schreibersii*.⁴⁰⁰ Historical records indicate isolation of lyssaviruses from bats in India and Thailand,^{544,665} and serologic surveys demonstrated the presence of lyssavirus antibodies in bats from the Philippines, Cambodia, Thailand, and Bangladesh.^{24,457,587} Presumed human rabies of bat origin was reported from China, although no virological examination was performed.⁶⁹² Indeed, significant surveillance efforts are needed in this large part of the world to elucidate ecology and epidemiology of lyssaviruses.

In Africa several divergent lyssavirus species have been documented. Dog rabies is widely distributed and represents the major burden for humans and domestic animals. At least three phylogenetic lineages of dog RABV were described, along with a separate lineage associated with mongooses.^{165,473,725} Epizootics in dogs frequently spread to wildlife.⁴²⁹ Several outbreaks have been described that significantly reduced populations of such

endangered species as African wild dog (*Lycaon pictus*)^{258,318} and Ethiopian wolf (*Canis simensis*).^{353,578} Another African lyssavirus, MOKV, has been sporadically isolated from shrews, domestic cats and dogs, and a rodent in various localities of Sub-Saharan Africa.^{370,473,513} MOKV is the only lyssavirus species never documented in bats. However, the principal reservoir host of this virus is still unknown. Two human cases of MOKV infection were documented via active surveillance efforts, both with unknown exposure history.^{210,211} In contrast to MOKV, LBV is clearly associated with bats from the *Pteropidae* family, such as *Eidolon helvum*, *Rousettus aegyptiacus*, *Micropteropus pusillus*, *Epomophorus wahlbergi*, and likely others, with only infrequent spill-over infections into terrestrial mammals, such as cats, dogs, and a mongoose.^{403,472,473} LBV is broadly distributed in Sub-Saharan Africa and at least once was translocated to France with *R. aegyptiacus* fruit bats, imported from Togo or Egypt.²⁸ The other two African bat lyssaviruses are less studied. Of the four known isolates of DUVV, three came from humans, who died of rabies after bites of insectivorous bats in South Africa and Kenya, and only one was obtained from a bat, presumably of the *Miniopterus* genus, in Zimbabwe.^{375,494,552,724} The last member of the genus, SHIBV, is known by a single isolate, obtained from an insectivorous bat *Hipposideros commersonii* in Kenya.⁴⁰² Indeed, more studies are needed to understand ecology and epidemiology of African non-RABV lyssaviruses.

Prior to 1996, Australia had been considered free of rabies and rabies-like viruses. An outbreak of rabies involving several dogs occurred in the island state of Tasmania in 1867 but was quickly eradicated. Since then, only a few imported rabies cases were registered. Following the discovery that flying foxes were a reservoir of Hendra virus, surveillance of these animals was increased, which resulted in the discovery of ABLV in 1996.^{247,272} ABLV has been identified in all four flying fox species in continental Australia: *P. alecto*, *P. poliocephalus*, *P. scapulatus*, and *P. conspicillatus*, in locations along the eastern coastal territory of the continent, where the surveillance was enhanced.²⁸⁷ Further, a distinct ABLV variant was identified in insectivorous bats *Saccolaimus albiventris*.²⁷³ Two human cases of ABLV infection have been described to date. The first, documented in 1996, was caused by the insectivorous bat ABLV variant,^{14,273} and the other one was caused by the pteropid ABLV variant.⁷⁴⁸ Both cases were fatal, and clinical symptoms were compatible with rabies. The distribution range of *P. alecto* bats extends into Papua, New Guinea, and the eastern islands of Indonesia.²⁴⁷ There is no reason to expect that distribution of ABLV is limited to continental Australia. For example, the presence of antibodies to this virus was demonstrated in 9.5% bat serum samples collected in the Philippines.²⁴

Epidemiology of Vesiculovirus Infections

The mechanisms of VSV transmission are not completely understood. Ecologic factors and special conditions regarding the host and the etiologic agent have been implicated in the clinical presentation of the disease.^{294–296} Experimental transmission from animal to animal by direct contact has produced irregular results. The virus is unable to penetrate intact skin or mucosa; for a successful transmission, it needs to be introduced beneath the skin and mucous membranes via wounds and abrasions.^{295,356} The virus can also be transmitted by the bite of insect vectors such as mosquitoes (*Aedes* spp.),^{701,751} sand flies (*Lutzomyia* spp.),¹⁴¹ blackflies (*Simulium* spp.),¹⁵⁶ and other *Diptera*.²²⁶ Virus isola-

tions from nonbiting insects (e.g., *Musca domestica*) have been reported.²⁴⁶ Many potential biological vectors of VSV have been suggested, but the phlebotomine sand fly, *Lutzomyia shannoni*, is the only one confirmed in the United States.⁷⁵¹

The disease is present only in the Western Hemisphere, and it is enzootic in southern Mexico, in Central America, in some regions of South America,⁷⁵⁰ and on Ossabaw Island, off the coast of Georgia.⁶⁷³ In temperate zones, VSV outbreaks begin in late summer and end with the arrival of frost.²⁷⁰ In the United States, the outbreak during 1982–1983 was unusual because it continued throughout the winter months until the following spring.⁸⁷ In tropical areas, the disease appears at the end of the rainy season and disappears with the advent of the dry season.⁷⁵¹ Typically, the disease affects only horses, cattle, and swine. During outbreaks, morbidity rates in a herd usually range from 10% to 15%.⁷⁵⁰ Cattle generally recover in a few days, but horses and pigs can develop lameness.^{295,750} A broad spectrum of wild mammals can also be affected.⁷⁵⁰ Factors that influence the disease spread in dairy cattle include coarse roughage, hard pelleted concentrates, poor general and milking hygiene, and insufficient teat sanitation.²⁹⁴ In the southeastern United States, feral swine had 10% to 100% antibody prevalence from 1979 to 1985⁶⁷⁴ and on Ossabaw Island showed 12% and 60% seroconversion between June and September in 1982 and 1983, respectively.⁶⁷⁵ In some enzootic areas of Central America, over 80% of the cattle have antibodies against VSV, but only 9% of the animals may present clinical signs in a particular year. In the same regions, wildlife also have a high VSV seroprevalence. In tropical areas where the disease is enzootic, VSV seroprevalence in the human population can be as high as 48%.³⁵² Serologic studies during outbreaks in Panama demonstrated a seroprevalence of 71% and 34% in personnel working with infected and noninfected cattle, respectively.⁸⁹ A similar situation has been observed during VSV outbreaks in Colorado, where personnel (veterinarians, researchers, and regulatory staff) handling sick livestock showed an antibody prevalence of 13%, whereas unexposed humans had a 6% seroprevalence.⁵⁸⁶

The mechanism by which VSV is maintained in enzootic regions is not fully understood. Sand flies may transmit the virus from a reservoir (e.g., plants, wildlife, cattle) to livestock. Alternatively, VSV may be maintained in the sand fly population by transovarial transmission, and the insects infect susceptible animals during feeding.¹⁴¹ In some enzootic areas, feral swine have been suggested as a potential amplifying host.⁶⁷³ Molecular epidemiologic studies indicate that enzootic areas may be the origin of the virus responsible for outbreaks in epizootic zones.⁵¹⁷ VSV may be introduced in a particular area by the movement of infected animals, wildlife, or insects, but the actual mechanism is unknown. Viruses circulating in enzootic areas present a high genetic diversity, with several lineages coexisting in the same region.⁵¹⁶ Within enzootic areas, the viruses seem to adapt under selective pressures exerted by ecologic factors. Viruses from different ecologic areas within enzootic regions belong to different genotypes. Viral adaptation to different insect vectors or mammalian reservoirs might be determinant factors for this divergent evolution.⁵⁹⁷ Viruses obtained from a particular outbreak are genetically homogeneous.⁵¹⁷

Epidemiology of Ephemerovirus Infections

Bovine ephemeral fever is distributed throughout Africa, the Middle East, Southeast Asia, and northern Australia.⁶⁷¹ It has

never been reported in the Americas. The disease occurs during summer and autumn and disappears with the arrival of the first frosts in subtropical areas. In the tropics, yearly occurrence is associated with the rainy season.^{671,735} Although transmission of the virus occurs via insect vectors, the difficulty of isolating the virus from insects hampers the recognition of the vector species involved in its transmission. BEFV was isolated from *Culicoides* spp. and from mosquitoes. In Australia, the geographic range of the disease is greater than that of the *Culicoides* species from which the virus was isolated. Two species of mosquitoes, *Culex annulirostris* and *Anopheles annulipes*, may be implicated in transmission in these areas.⁶⁷¹ In general, morbidity is low, but in some outbreaks, all of the animals in a herd may be affected. In other instances, only 2% or 3% of the animals show clinical signs.^{671,735} Natural disease occurs only in cattle and water buffalo. Although seroprevalences of 13% to 38% were reported in cattle in enzootic areas, a higher prevalence of 64% has been observed during outbreaks.¹⁶¹ The role of wild ruminants in the maintenance of BEFV in nature is not understood. Seroprevalences between 28% and 54% are found in wild ruminants in Kenya, Zimbabwe, and Tanzania.^{18,166}

Epidemiology of Novirhabdovirus Infections

Novirhabdoviruses cause severe economic losses to the salmonid farming industries.^{317,786} As was described earlier, IHNV is endemic to western North America, and dispersal of the virus outside North America has occurred by inadvertent transport of infected eggs and juvenile fish.^{313,373,617} Within North America, dispersal of IHNV is thought to have involved the historical use of unpasteurized salmon viscera in feed for salmon hatcheries, and possibly the historically common practice of salmon transplantations.^{102,749,786} Following the introduction to the Eastern Hemisphere, European and Asian IHNV isolates demonstrate relatedness to specific phylogenetic lineages within the endemic area from which they were derived.^{372,521,540}

VHSV was first discovered in Western Europe.⁷⁸⁶ So far, VHSV has been isolated from over 60 fish species from both marine and freshwater habitats representing North America, Asia, and Europe.⁶⁵⁴ VHSV is endemic to numerous marine species in both the Atlantic and Pacific Oceans of the northern hemisphere and could have been introduced into freshwater habitats by marine fish species (e.g., herring, sprat, sand eel) that are used as fresh feed for commercial farming in some countries.⁶⁵⁴ The freshwater isolates of VHSV appear to be evolving ~2.5 times faster than the marine isolates.²⁰⁰ The successful recent viral adaptation in new hosts is one of the possible explanations for such higher evolutionary rates of VHSV in freshwater fish.⁵⁰⁵ Alternative explanations for the increased substitution rates in freshwater VHSV are the intensive aquaculture practices and the higher water temperature in culture ponds, which could cause an increase in virus replication rates.²⁰⁰ A similar pattern has also been observed for IHNV in North America, where the evolutionary rate was found to be three to four times higher in regions with intensive aquaculture, as compared with other regions.⁷¹²

HIRRV was first isolated in Japan from Japanese flounder³⁷⁴ and subsequently was also reported in Korea.^{371,534} It has recently been reported to infect several other fish species endemic to Japan.³⁷⁴ SHRV was first isolated from snakehead

fish in Thailand and has not been reported outside Southeast Asia to date.³⁶³

CLINICAL FEATURES OF RHABDOVIRUS INFECTIONS

Lyssavirus Infections

Rabies cases are almost always attributable to the bite of a rabid animal. For example, animal bites were the cause of 99.8% of 3,920 human rabies cases examined at various Pasteur Institutes between 1927 and 1946.⁴⁸⁷ Nonbite exposures, which rarely cause rabies, include inhalation of aerosols,^{325,333,781} licks,⁴²⁴ transdermal scratches, or other unusual events that lead to contamination of an open wound or mucous membrane,²³² such as tissue or organ transplantation.^{344,669} Bat RABV-associated human deaths in the United States may not have a reported exposure source,^{112,522} but these cases are most likely caused by bat bites in which either the risk was not appreciated or the bites were not immediately recognized by the patient. Disease development after exposure depends on the location and severity of a bite, the species of animal responsible for the exposure, and the virus variant.^{29,40,518,649,726} In the absence of vaccination, the highest mortality tends to occur in persons bitten on the head and face (40% to 80%), with intermediate mortality in those bitten on the hands or arms (15% to 40%), and least in those bitten on the trunk or legs (5% to 10%) or through clothing (less than 5%).^{29,637,652,726}

The incubation period (the length of time between exposure to virus and development of clinical signs) is usually 1 to 2 months.^{232,744} Because it can vary from less than a week^{307,551,560} to several years,^{10,33,662,770,774} rabies is one of the most variable infectious diseases. The length of the incubation period may depend on the bite site and relative proximity to the CNS,^{10,350,687} severity of the bite, type and quantity of virus introduced, host age, and immune status.^{10,19,194,205,301,304,487,519,649}

Development of clinical rabies in humans can be divided into three general phases: a prodromal period, the acute neurologic phase, and coma preceding death.^{232,307} During the prodromal period, lasting 2 to 10 days, symptoms are usually mild and almost entirely nonspecific; they include general malaise, chills, fever, headache, photophobia, anorexia, nausea, vomiting, diarrhea, sore throat, cough, and musculoskeletal pain. One specific early symptom is abnormal sensation around the bite site, such as itching, burning, numbness, or paresthesia.¹⁹⁴

During the acute neurologic phase, patients exhibit signs of nervous system dysfunction such as anxiety, agitation, dysphagia, hypersalivation, paralysis, and episodes of delirium. Occasionally, priapism or increased libido may be observed.¹⁹⁸ Cases in which hyperactivity is predominant are classified as *furious* rabies. When paralysis dominates, it is classified as paralytic or *dumb* rabies.^{125,380,727} From 17% to 80% of patients exhibit hydrophobia, a pathognomonic sign of rabies believed to be caused by an exaggerated respiratory tract protective reflex.^{10,19,746,774} Hydrophobic episodes, initially triggered by attempts to drink,^{307,774} can last from 1 to 5 minutes. In furious rabies, the neurologic period ends after 2 to 7 days with coma or sudden death from respiratory or cardiac arrest.⁷⁶

Paralytic rabies occurs in about 20% of patients and may be more frequent in persons exposed to certain strains, such

as vampire bat RABV.³²⁸ In marked contrast to furious rabies, the sensorium is largely spared.^{309,328} Patients initially develop paresthesia and weakness, and finally flaccid paralysis, usually in the bitten extremity.¹²⁵ Paralysis progresses to paraplegia and quadriplegia. In paralytic rabies, the course is usually less rapidly progressive, with some patients living up to 30 days without intensive care.⁴⁵³ The final stage of the disease is coma, which lasts 3 to 7 days and results in death.⁷⁶ In patients receiving respiratory assistance, survival may be prolonged for weeks,^{76,522} with death caused by other complications.^{65,204,301}

To date, six cases of human recovery from clinical rabies have been documented. Five had exposure to animal bites,^{15,300,565,773} and one occurred after suspected inhalation of rabies virus in the laboratory.¹¹⁰ Only one of these occurred in a patient who had never been vaccinated,⁷⁷³ whereas the other five cases were attributed as exposures and vaccination failures. In the nonvaccinated patient, an experimental treatment included induction of ketamine coma in conjunction with antiviral compounds and intensive care.⁷⁷³ Nevertheless, more than 10 attempts to repeat such experimental treatment (although with deviations and modifications) failed.³³⁸ However, in one vaccination failure case (immunoglobulin was not administered, although all five doses of vaccine were administered on time), the experimental treatment was implemented successfully.¹⁷⁴ In addition, this was the only survival case where the virus variant was identified (vampire bat RABV). In all other survivors neither antigen detection nor virus isolation nor RNA amplification was successful, and rabies diagnosis was based on the history of exposure, compatible incubation period and clinical signs, and serologic tests. Another case of presumptive abortive rabies infection in a human, who never required intensive care, and only once received rabies biologics after establishment of the diagnosis, was reported recently.¹¹³

Clinical disease in animals is not unlike that of humans, except for the absence of hydrophobia. Signs are variable but can include altered phonation, pica, cranial nerve deficits, altered activity patterns, and loss of fear of humans.³⁷

Vesiculovirus Infections

In natural infection, the incubation period of vesiculovirus varies from 2 to 9 days, but usually lesions develop between 2 and 5 days after exposure.^{303,356} The lesions of vesiculovirus are indistinguishable from those of FMD. In cattle, the initial lesions are characterized by pink to white papules in the mouth that progress in 1 to 2 days to vesicles. The vesicles can coalesce and rupture, leaving a denuded area that heals in 1 or 2 weeks if no secondary infections occur.³⁵⁶ These lesions can also occur in the dental pad, lips, gums, muzzle, nose, teats, and feet. In experimental inoculation of horses, vesicles appeared in the mouth 42 hours after inoculation, and 2 days later, part of the dorsal epithelial covering of the tongue sloughed off. Vesicles also appeared on the feet. At necropsy, the spleen was enlarged, but no other lesions were observed in the internal organs.¹⁴⁸ In natural infection of horses, lesions are found in the lips, corners of the mouth, muzzle, nostrils, ears, belly, prepuce, and udder.³⁰³ The lesions in pigs are similar to those described for cattle.²⁹⁶ Affected animals have increased salivation and a sharp reduction in milk production. Eating is difficult because of the sore mouth, with a consequent decline in physical condition. Lameness develops with foot lesions.

Although development of secondary lesions in places other than the point of inoculation is suggestive of viremia, the virus has not been isolated from blood even at 6 hours after the experimental inoculation of pigs.^{133,583,672} The virus is present at its highest titer in the vesicular fluid, which represents a transient but very efficient source of virus for contact transmission. The virus can be isolated from specimens taken from saliva, tonsils, vesicular fluids of feet, and, in some cases, feces.^{133,583,672}

Ephemerovirus Infections

After an incubation period of 2 to 4 days, the first clinical sign is fever (40°C to 42°C), accompanied by malaise and a severe drop in milk production. In 12 to 24 hours, fever remits, followed by a second febrile phase. During this second phase, the animals are depressed, are anorexic, and show muscle stiffness and lameness. Ruminal stasis, nasal and ocular discharges, and swelling of one or more joints are present. Subcutaneous emphysema can develop in some animals.^{671,735} The clinical signs persist for 1 or 2 days, followed by rapid recovery. Clinical signs are much more severe in adults than in calves. Calves under 6 months of age show no clinical signs.⁷⁸

Novirhabdovirus Infections

Viral hemorrhagic septicemia (VHS) generally occurs at temperatures between 4°C and 14°C. At water temperatures between 15°C and 18°C, the disease generally has a short course with a modest accumulated mortality. VHS rarely occurs at higher temperatures. Low water temperatures (1°C to 5°C) generally result in an extended disease course with low daily mortality but high accumulated mortality. For IHNV, the temperature optimum is slightly greater, 3°C to 18°C. VHS outbreaks occur during all seasons but are most common in spring when water temperatures are rising or fluctuating. For more detailed reviews of the condition see, Smail⁶⁵⁶ and Wolf.⁷⁸⁶

VHS progresses in three stages. The acute stage includes a rapid onset of high mortalities (up to 90%, particularly in young fish) often with severe clinical signs such as darkening of body color, exophthalmia (bulging eye), bleeding around eyes and fin bases, pale gills, and petechial (pinpoint) hemorrhaging on the surfaces of the gills and viscera and in the muscle. Virus multiplication in endothelial cells of blood capillaries, hematopoietic tissues, and cells of the kidney underlies the clinical signs. Gross pathology includes generalized petechial hemorrhaging in the skin, muscle tissue (especially in dorsal muscles), and internal organs.⁵³¹

During the second subacute, or chronic, stage, the body continues to darken and exophthalmia may become more pronounced, but hemorrhaging around the eyes and fin bases is often reduced. Fish are severely anemic and paleness is particularly evident in the abdomen. Fish may develop a spiraling swimming motion. The final, nervous stage involves reduced mortality and clinical signs are usually absent, but the corkscrew swimming motion becomes more pronounced. The disease is transmitted horizontally through contact with infected fish or water. Large amounts of virus are shed in the feces, urine, and sexual fluids. There is no vertical transmission of the VHSV. However, vertical transmission has been documented for IHNV.⁵³⁰ Virus is shed from infected fish via the urine⁶⁵⁶ and reproductive fluids and can also be transferred by piscivorous birds as external mechanical vectors.^{536,559} Incubation time is dependent on temperature and dose; it is 5 to 12 days at

higher temperatures. During and immediately following an outbreak, virus can be isolated readily from kidney, heart, and spleen tissues.

VHSV can also establish a carrier state in freshwater fish species.^{206,355} The virological status of such carriers will be dependent on a range of parameters including the length of time following initial exposure and geographical proximity to fish-farm outlets. Based on virus isolation in cell culture, the prevalence of VHSV in marine fish species has been found to be in the range of 0.0% to 16.7%.⁶⁵⁴

DIAGNOSIS OF RHABDOVIRUS INFECTIONS

Lyssavirus Infections

Clinical diagnosis of rabies is not difficult in cases of a documented history of exposure and subsequent compatible clinical signs or symptoms. Because an exposure history may be lacking, rabies should be considered in any acute, unexplained neurologic disease that rapidly progresses to coma and death.³⁸ Routine diagnosis is established by standard laboratory tests for specific virus isolates, antigens, nucleic acids, or neutralizing antibodies.^{293,659,745} Postmortem diagnosis should be performed on CNS specimens, especially the brainstem and cerebellum.⁶⁹⁷ The fluorescent antibody test⁶⁵⁹ and the avidin-biotin immunohistochemical technique²⁸⁹ are sensitive and specific methods for detecting virus antigen (Fig. 31.12).

Examination of skin biopsies from the face⁹⁶ or hair-covered occipital portions of the neck for virus antigen^{77,522} is

FIGURE 31.12. Immunohistochemical staining of intracytoplasmic viral inclusions in the neuron of a human rabies patient (630×). (Courtesy of M. Niezgodna, CDC/OID/NCEZID/DHPP/PRB.)

a rapid method to diagnose human rabies before death. Rabies virus can be isolated from saliva by direct intracerebral inoculation into mice³⁸⁷ or by infection of neuroblastoma cells.⁶⁵⁷ Fluorescent antibody examinations of corneal impressions may occasionally lead to the diagnosis of human rabies.³⁸¹ The reverse transcriptase-polymerase chain reaction (RT-PCR) assay has been used to amplify and sequence parts of the lyssavirus genome directly from brain, saliva, and other affected tissues.^{138,302,522,659} This allows detection of rabies virus-specific RNA and also permits insights into the identity of the virus variant by genetic sequencing. Detection of specific antibodies in serum^{522,662} late in the clinical course can be diagnostic for rabies, if the patient has not been previously vaccinated. Except for certain cases of postvaccinal encephalomyelitis, CSF antibodies are produced only in rabies-infected, not in vaccinated, individuals.⁷⁴⁷ Several diagnostic tests have been developed for detection of virus-neutralizing antibodies, such as the rapid fluorescent focus inhibition test (RFFIT) and the fluorescent antibody viral neutralization (FAVN) test, which are recommended by national and international authorities, such as the World Health Organization (WHO), Office International des Epizooties (OIE), and Advisory Commission on Immunization Practices (ACIP).^{137,323,658} Recently, lentiviral pseudotypes containing glycoproteins of different lyssaviruses have been developed for replacement of infectious RABV in such virus-neutralizing tests.⁷⁹¹ Several modifications of enzyme-linked immunosorbent assays (ELISAs) have been developed for capture and measure of antiglycoprotein antibodies of RABV.^{639,753,810} However, such ELISA-based tests are currently not recommended for the cases where diagnostic accuracy is critical.⁵⁰¹ Other serologic methods have been developed that detect antibodies against other components of RABV, primarily the nucleocapsid, which is most abundant in the infected cells. Of these, the best established is the indirect fluorescent antibody test (IFA). Antibodies detected by IFA appear earlier than virus-neutralizing antibodies and sometimes are the only positive result obtained antemortem.^{113,659,662}

Vesiculovirus Infections

Because vesiculovirus is clinically similar to FMD, differential diagnosis between the two diseases is of utmost importance, especially in countries free of the latter disease. VSV can be isolated from vesicular fluid or epithelium of the lesions by inoculation in mice, embryonated eggs, or cell culture.¹³⁴ The virus can be identified by virus neutralization, complement fixation, or immunofluorescence.²⁹⁶ Complement fixation provides a rapid, sensitive, and accurate method for the differentiation of VSV and FMD virus.²⁹⁵ A rise in virus neutralization or ELISA antibody titer in serum samples taken during the clinical and convalescent phases of the disease is evidence that the infection was caused by VSV.¹³ Recently, detection of VSV in clinical samples by RT-PCR has been described. This method is highly sensitive and specific, providing a rapid diagnosis and material for genetic characterization of the virus.^{319,598}

Ephemerovirus Infections

Clinical diagnosis of BEF is based on its rapidity of spread and transient nature.⁷⁸ For confirmation, virus isolation or the demonstration of an increase in virus neutralization or ELISA antibody in paired serum samples is needed.¹⁸⁷ A blocking ELISA compares favorably with neutralization and does not detect

cross-reacting antibodies to Kimberly or Berrimah viruses.⁸⁰⁵ Although impractical for routine diagnosis, cattle inoculation with blood from BEFV-affected animals is the most sensitive method for viral isolation. Isolation of BEFV in *Aedes albopictus* cells from the blood of infected animals, followed by direct immunofluorescence to detect the presence of viral antigens, has been used in experimental studies.⁷²⁰

Novirhabdovirus Infections

The occurrence of clinical signs of VHS described earlier should suggest the presence of IHNV and VHSV. Gross pathology includes generalized petechial hemorrhaging in the skin, muscle tissue (especially in dorsal muscles), and internal organs. Histopathologic findings reveal degenerative necrosis in the hematopoietic tissues, kidney, spleen, liver, pancreas, and digestive tract. Necrosis of eosinophilic granular cells in the intestinal wall is pathognomic of IHNV infection.⁸⁰ The kidney, liver, and spleen show extensive focal necrosis and degeneration—cytoplasmic vacuoles, pyknosis, karyolysis, and lymphocytic invasion. In case of VHSV, diagnosis can involve immunohistochemistry analysis of VHSV-positive endothelial cells in the vascular system.²⁰⁹ The standard surveillance method to detect carrier fish for IHNV and VHSV is based on direct isolation of the virus in cell culture followed by identification using antibody-based methods (IFA, ELISA) or nucleic acid-based methods (e.g., RT-PCR), followed by gene sequencing. PCR-based detection of viral genomes in fish tissue is still under development. The technique can be used for confirmation of overt infection in fish but has yet to be validated for use in direct surveillance programs.^{22,25,172,186,416,784}

PREVENTION AND CONTROL OF RHABDOVIRUS INFECTIONS

Lyssavirus Infections in Humans

Rabies has the highest case-to-fatality ratio of any infectious disease. With rare exceptions, comfort care, sedation, and life support measures may prolong life but do not prevent death. In most situations, use of the term *treatment* is a misnomer and refers to medical aid related to animal bite and disease prevention by postexposure prophylaxis.⁷⁶⁷ However, the establishment of a protocol for experimental treatment of clinical rabies⁷⁷³ has led to more attempts to combat the clinical disease. The majority of these have failed,³³⁸ although at least one positive result, with recovery of the patient, was reported.¹⁷⁴ Indeed, more studies in suitable animal models are needed to investigate different components of the protocol, potential ways of their modifications, and improvements.³³⁸ More than 12 million humans are exposed and may undergo antirabies prophylaxis annually, but in excess of an estimated 50,000 to 100,000 die, primarily from the bite of an infected dog.^{495,719} Regional epidemiologic surveillance and knowledge of viral pathogenesis, development of vaccination algorithms, and communication of risk to different occupational groups can significantly reduce human morbidity from inappropriate prophylaxis and rabies mortality.^{643,778} Eliminating primary exposure to rabid animals is a fundamental means of rabies prevention. Human rabies deaths are infrequent in regions with controlled canine rabies. Nevertheless, tens of thousands

of potential exposure cases are treated annually in Europe and North America because of enzootic wildlife rabies.²⁹³

Postexposure prophylaxis in humans includes proper wound care and the administration of rabies vaccine and antirabies immune globulin.^{111,790} Although the inclusion of antirabies serum or immune globulin in the prophylaxis protocol is not new,¹⁰³ it is infrequent. Most cases of human rabies prophylaxis in Africa, Asia, and Latin America are with vaccine only,⁴⁹⁶ often a nervous system tissue vaccine.^{43,349,415,523,562} Cell culture-based rabies vaccines (e.g., human diploid cell rabies vaccine [HDCV]) are used in much of the developed world and form the standard for historical comparison with the Pasteurian neural vaccines from the 19th century,^{731,767} including its later phenolized derivatives (Fermi, Semple, and others). Inactivated cell culture-based vaccines⁶⁸² and antirabies immune globulin, which are major improvements over cruder biologicals, decrease the adverse events related to anaphylaxis or serum sickness.^{412,769} Other major rabies vaccines are produced in avian embryo fibroblasts (e.g., purified chick embryo cell culture rabies vaccine [PCEC], Rabipur) or in rhesus monkey kidney cells (purified Vero cell rabies vaccine [PVRV], Verorab), with aluminum phosphate as an adjuvant.⁷⁹⁰ Production of HDCV is relatively difficult, with limited viral yields, resulting in high production costs. Primary hamster kidney cell vaccines are used in Russia, China, and other parts of Asia.⁴⁴⁵ Efficacy trials using reduced doses, different immunization schedules, and alternative routes (e.g., intradermal administration) have been conducted and have demonstrated both high efficacy and safety.^{129,130}

At present, no evidence suggests that prophylaxis failure is caused by antigenic variation of RABV.⁷⁹⁰ Rather, vaccine failures are usually associated with inadequate wound care, omission of potent serum, failure to infiltrate the wound with immune globulin, delay, or failure to follow recommended procedures.^{308,545,585,771} Future tactics for global human rabies prevention will continue to focus on the need for enhanced public health communications; continuing professional education; potent, inexpensive pre- and postexposure vaccines^{250,412,413} and new schedules; and viable alternatives to rabies immune globulin (e.g., monoclonal antibodies).⁴⁶ Based on the recognition that rabies at its source can be effectively controlled and sometimes eliminated, safer, more effective, and inexpensive veterinary vaccines are a necessity for animal reservoirs, vectors, or victims of the disease.^{38,100,220,222,235,780,790}

Although available rabies biologics provide reliable protection against phylogroup I lyssaviruses (RABV, DUVV, EBLV-1, EBLV-2, ABLV, ARAV, KHUV, DUVV), they do not protect against phylogroup II lyssaviruses (LBV, MOKV, SHIBV) or against WCBV, because of the significant antigenic differences.^{34,291} Given broad distribution of the latter divergent lyssaviruses in Africa, in southeastern Europe, and perhaps more widely in the world,^{81,402,403,473,513} there is a need to develop new biologicals, capable of providing reliable protection against them.

Control of Rabies in Animals

Rabies is not considered a serious candidate for disease eradication at this time because of numerous and diverse wild reservoirs.¹¹² The correlation between canine rabies and human fatalities, however, has led to the successful application of domestic animal vaccines, particularly in developed countries.¹⁰⁰

A comprehensive domestic animal program also requires responsible pet ownership. Such a program entails stray animal management; leash law amendments; humane population curtailment (e.g., early spay and neuter programs); animal importation, translocation, and quarantine regulations; schedules for early pre-exposure vaccination of companion animals (in light of potential maternal immune inhibition); and rational post-exposure management.¹¹¹ Unlike postexposure prophylaxis of humans, euthanasia is usually recommended for the naïve animal exposed to rabies, but this may eventually change with the development of safe and effective biologicals and protocols.

Current veterinary vaccines are more potent than earlier attenuated and inactivated vaccines.^{26,567} Because no vaccine is 100% effective, given poor cross-reactivity with some viral species,^{291,733} and because correct identification of the properly immunized animal may be confusing, the vaccinated dog or cat is not exempt from confinement and close observation. This strict period of observation of the biting animal applies to dogs, cats, and, in some countries, domestic ferrets.¹¹¹ Human prophylaxis may be delayed during this time in areas that are not enzootic for canine rabies.⁶⁵³ In addition, pet vaccination status does not necessarily alter the need for euthanasia of an offending animal, regardless of vaccine potency or efficacy, if rabies is suspected.

In the case of free-ranging, nondomestic mammals, population reduction of major rabies reservoirs has been practiced for centuries but has not been generally regarded as a humane, long-term, cost-effective, or ecologically sound tool to control widespread lyssavirus infection.^{171,293} Anticoagulants, however, have been used successfully to control hematophagous bats in Latin America. Anticoagulants have been applied topically to bite wounds on cattle, followed by systemic treatment of exposed cattle, and finally topical treatment of vampire bats themselves, exploiting their behavior of mutual grooming at the roost.²³⁹ These control efforts can avoid the destruction of beneficial nontarget bat species, perhaps some day to be augmented with novel vaccination strategies.⁶⁴⁰

For more than four decades, efforts have been made to protect free-ranging wildlife against virulent street virus by oral consumption of vaccine contained within bait.⁷⁸⁰ Millions of rabies virus vaccine-laden baits have been distributed over rural and urban areas in western Europe, eastern Canada, and the United States for wildlife rabies control.^{27,36,235,419,601,602,738} Historically, attenuated rabies virus strains (such as ERA, SAD) were broadly used for oral vaccination of wild carnivores in Western Europe and North America.^{626,739} However, sporadically these vaccine strains caused rabies in wildlife.^{216,508} A vaccinia-rabies glycoprotein (V-RG) vaccine was the first recombinant rabies vaccine to be constructed, field tested, and considered for regulation in Europe and North America for wildlife rabies control. This vaccine has been extensively reviewed to ensure safety (tested in more than 40 species of mammals and birds) and efficacy (proved against severe rabies challenge in target species). Thermostability of the vaccine has been demonstrated under laboratory and field conditions. Following the success of the V-RG vaccine against fox rabies in Belgium⁸⁸ and France, preliminary field trials suggest its potential utility for rabies control in raccoons, foxes, and coyotes in the United States.^{215,292,591,603} Other orthopoxviruses have been considered as vectors of lyssavirus antigens, but these have not yet been field tested.^{217,450} A number of

attenuated and recombinant rabies vaccines have been developed.^{36,69,235,408,423,547,612,613,768} Oral vaccines have been successfully developed for red, Arctic, and gray foxes; coyotes; raccoon dogs; raccoons; skunks; and domestic dogs.^{88,221,241,526,613} If future recombinant, replication-incompetent, inactivated, or DNA-based vaccines^{208,343,420,449,500,538,613,795} prove both efficacious and economical, they may render most previous biosafety concerns obsolete, paving the way for more widespread, free-ranging wildlife and dog rabies control, particularly in developing countries. Another promising approach is combination of rabies vaccination with immunocontraception, which can significantly reduce the population of the disease vectors, particularly stray dogs.⁷⁹²

Control of Vesiculovirus Infections

Supportive veterinary care of affected animals helps to prevent complications that can delay recovery from VSV infection. Vaccination against VSV has been practiced to only a limited extent. A modified live vaccine, attenuated in cell culture or chicken embryos, has been used in parts of the United States, Central America, and Peru. This vaccine, administered intramuscularly in cattle, protects from disease for at least 1 year.²⁹⁶ During the 1985 epizootic in Colorado, an inactivated VSNJV vaccine was used in the field and later tested in an experimental trial. It induced antibodies that lasted for 175 days, but viral challenge was not performed to assess protection.²⁶⁵ Recently, a recombinant vaccinia virus expressing the VSV-I glycoprotein was developed and used experimentally to immunize cattle. Inoculated animals developed antibodies and resisted intradermal lingual challenge.⁴⁶⁹

Control of Ephemerovirus Infections

Vector control of BEFV is very difficult. International efforts to prevent the introduction of disease and vaccination may be the only practical methods for prevention of BEF.⁷³⁵ Several attenuated vaccines, produced by serial passage in mouse or cell culture, provided protection against experimental challenge when mixed with adjuvants and given in several doses.⁶⁷⁰ Inactivated vaccines were developed in Japan and Australia, but they induced poor and unreliable immunity. Vaccinia virus expressing the G protein elicited neutralizing antibodies in cattle, which were resistant to a subsequent viral challenge.³¹² Additionally, an experimental subunit vaccine consisting of purified G protein mixed with Quil adjuvant conferred protection against viral challenge.⁷²¹

Control of Novirhabdovirus Infections

Control methods for IHNV currently rely on avoidance of exposure to the virus through the implementation of strict control policies and sound hygiene practices.⁷⁸³ The thorough disinfection of fertilized eggs, the use of virus-free water supplies for incubation and rearing, and the operation of facilities under established biosecurity measures are all critical for preventing infectious hematopoietic necrosis at a fish production site.

Vaccination of salmonids against IHNV is at an early stage of development; however, a range of vaccine preparations have shown promise in both laboratory and field trials.^{397,782} Both autogenous, killed vaccines and a DNA vaccine have been licensed for commercial use in Atlantic salmon net-pen aquaculture on the West Coast of North America, where such vaccines can be delivered economically by injection. Vaccines

against IHNV have not yet been licensed in other countries, where the application of vaccines to millions of small fish will require additional research on novel mass delivery methods. Although research on vaccine development against VHSV has been ongoing for more than three decades, a commercial vaccine is not yet available. DNA-based vaccines have proven to be very promising, inducing good protection from VHS.⁴⁵² Several immunostimulants, such as yeast-derived β -glucans, IL-1 β -derived peptides, and probiotics, have been assessed for enhancing protection against VHS.⁵⁵⁴ Disinfection of eggs is a highly effective method to block egg-associated transmission of novirhabdoviruses in aquaculture settings.⁷⁸³ The method is widely practiced in areas where the virus is endemic. Other experimental approaches include resistance breeding and restocking with a resistant fish species.^{310,783}

PERSPECTIVES

The foreseeable future for rhabdoviruses is for these viruses to occupy essentially the same positions in the science of virology that they have occupied for the past several decades—VSV as a well-studied prototype for the nonsegmented, negative-strand RNA viruses, RABV as a dreaded cause of disease in animals and humans, and the ephemeroviruses and novirhabdoviruses as important animal pathogens. Study of these viruses should continue to provide fundamental insights into the basis for virus–host interactions, neurotropism, and neuropathogenesis. In terms of the basic molecular biology of negative-strand RNA viruses, a number of important questions that have yet to be fully addressed have been pointed out through the course of this chapter. For example, the question of how the large, multifunctional L protein is able to respond to the many different *cis*-acting sequences that regulate its activity and the issue of how different intracellular nucleocapsids are selected for envelopment during the process of virus assembly are fundamental questions. In the area of virus–host interactions, the questions of viral virulence determinants and how rhabdoviruses suppress host responses among the different cell types involved in viral pathogenesis and immunity will be key questions for understanding the basis for viral pathogenesis in intact animals. In terms of the control of rabies, advances will come from the enhanced ability to control the spread of RABV among wild animal populations as well as the development of newer, more effective vaccine strategies.

One of the exciting areas of development with rhabdoviruses is the use of genetically engineered viruses as vaccine vectors or therapeutic agents. The use of recombinant VSV and RABV as vaccine vectors has been mentioned several times throughout the chapter.^{147,214,592,593,607,631} In addition, both VSV and RABV have potential use as cytolytic agents for therapeutic purposes. For example, genetically engineered strains of both VSV and RABV for cytolysis of HIV-infected cells have been generated, which lack G protein but express CD4 and chemokine receptors in the virus envelope.^{490,632} Another example of use of rhabdoviruses for cytolytic purposes is in the development of oncolytic viruses to treat patients with cancer. These viruses take advantage of the fact that many cancers appear to be defective in their ability to respond to antiviral cytokines, such as IFN.^{47,680} Such cancers are susceptible to viruses that induce host antiviral responses (e.g., M protein mutant viruses)^{3,681} or

viruses that encode antiviral cytokines (e.g., IFN- β , IL-4),^{224,527} whereas normal cells are largely resistant. Thus, these genetically engineered viruses have a greater selectivity for replication in cancers compared with normal tissues.

As a result of the efforts in developing recombinant rhabdoviruses as vaccine vectors and as cytolytic agents, it is likely that clinical trials of genetically engineered rhabdoviruses in humans will take place in the near future. For example, at least two genetically engineered VSVs have been considered by the National Institutes of Health Recombinant DNA Advisory Committee for potential oncolytic therapy in humans, a key step toward beginning clinical trials in a variety of cancer types.^{716,717} A number of issues need to be considered in the use of such agents, such as their safety for use in humans, as well as the protection of animal populations that may be exposed to such viruses. Nonetheless, the advances in understanding virus replication and pathogenesis should make it feasible to address these issues, so that these viruses that have long been a burden to humanity can instead be a benefit.

CLASSIFICATION

Taxonomy

Filoviruses are taxonomically classified within the order *Mono-negavirales*, a large group of enveloped viruses whose genomes are composed of a nonsegmented, negative-strand (NNS) RNA molecule.⁹⁸ Following their discovery, filoviruses were initially grouped with rhabdoviruses, based primarily on the appearance of virus particles. However, subsequent morphologic, genetic, physiochemical, and virologic studies of Marburg virus (MARV) and Ebola virus (EBOV) isolates revealed unique properties and led to their placement into a separate family, the *Filoviridae*.²²⁴ Further characterization of these agents demonstrated that EBOV and MARV represent divergent lineages of filoviruses; their differences were significant enough to warrant the formation of the genera *Marburgvirus* and *Ebolavirus*. According to the International Committee on Taxonomy of Viruses (ICTV) (<http://www.ictvonline.org/virusTaxonomy.asp?version=2009&xbhcp=1>), the *Marburgvirus* genus contains a single species, *Lake Victoria marburgvirus*, because strains exhibit only limited genetic variation. However, the appearance of distinct MARV lineages may lead to further speciation.⁴⁰¹ There is a greater divergence within the *Ebolavirus* genus, five species having been recognized: *Zaire ebolavirus* (type species; ZEBOV), *Sudan ebolavirus* (SEBOV), *Reston ebolavirus* (REBOV), *Tai Forest ebolavirus* (formerly Ivory Coast or *Cote d'Ivoire ebolavirus*, ICEBOV or CIEBOV), and *Bundibugyo ebolavirus* (BEBOV), of which BEBOV has still to be approved.⁴⁰³ A distinct filovirus sequence has recently been obtained from bats in Spain, but no virus has yet been isolated. This new "putative virus" (designated Lloviu virus) is proposed to represent the single species *Lloviu cuevavirus* in the new genus *Cuevavirus* of the *Filoviridae* family.²⁹⁹

Biosafety and Biosecurity

Because of their high mortality rate, their potential for person-to-person transmission, and a lack of an approved vaccine or antiviral therapy, MARV and EBOV are classified as biosafety level 4 (BSL-4; risk group 4) pathogens, for which maximum containment facilities are required when handling the infectious agent (<http://www.cdc.gov/biosafety/publications/bmbl5/BMBl.pdf>). Filovirus infectivity is quite stable at room temperature (20°C), but is largely inactivated in 30 minutes at 60°C; MARV is somewhat resistant to desiccation. Infectivity is greatly reduced or destroyed by high doses of ultraviolet light and gamma irradiation, lipid solvents, β -propiolactone, photo-induced alkylating probe 1,5-iodonaphthylazide, guanidinium isothiocyanate, and commercial hypochlorite and phenolic disinfectants.

The threat of bioterrorism in the aftermath of the September 11, 2001 and anthrax attacks against the United States has

prompted governments to implement countermeasures. This has led to greater restrictions on the acquisition and use of a variety of agents that pose serious threats to public health. Filoviruses have been classified as Centers for Disease Control and Prevention (CDC) Category A Agents (<http://www.bt.cdc.gov/agent/agentlist-category.asp#a>), as part of a system for prioritizing initial public health preparedness efforts and grading the potential of agents for large-scale dissemination. Filoviruses are also classified as “select agents” by the CDC Select Agent Program. This program is mandated by federal law to regulate

activities involving these agents within the United States and to register laboratories and entities handling one or more select agents (<http://www.cdc.gov/od/sap/>).

HISTORY

Table 32.1 lists the documented occurrences of MARV and EBOV disease, along with information regarding these outbreaks. Additional details of these episodes are described in the following sections.

TABLE 32.1 Outbreaks of Filovirus Disease

Filovirus (species)	Year	Outbreak location	Place of origin	Human cases (% mortality)
LVMARV	1967	Marburg/Frankfurt, Germany; Belgrade, Serbia	Uganda	32 (23)
	1975	Johannesburg, South Africa	Zimbabwe	3 (33)

	1992	Siena, Italy	Philippines	0 (0)
	1996	Alice, Texas	Philippines	0 (0)
	2008	Philippines	Philippines	0 (0)

Note, in 2012, Uganda has reported two EHF and one MHF outbreak; another EHF outbreak was reported from DRC. The EHF outbreaks were caused by SEBOV and BEBOV. The border region between Uganda and DRC seems to be a new “hot spot” for filovirus HF. For more information, please see the CDC and WHO websites.

^aFrom approximately 1998 to the present time, there have been partially confirmed reports of transmission of ZEBOV among great apes in Gabon and the Republic of Congo (RC), which has severely impacted gorilla and chimpanzee populations.

^bIncluded an imported case in South Africa where an ill Gabonese physician (survivor) infected a nurse who died.

^cCase fatality rate (CFR) was much higher if one considered only laboratory-confirmed cases.

^dREBOV has only been traced to a single monkey-breeding facility in the city of Calamba, Philippines, which was depopulated in 1996 and is no longer in operation. DRC, Democratic Republic of Congo; RC, The Republic of Congo.

Marburg Hemorrhagic Fever (MHF)

The first identified instance of filovirus disease occurred in 1967, when MARV caused severe cases of hemorrhagic fever in Europe.^{274,275,276} The epidemic started in mid-August in Marburg, Germany with three laboratory workers who contracted the disease after processing organs from African green monkeys (*Cercopithecus aethiops*) imported from Uganda. Seventeen more patients were hospitalized and two medical personnel contracted the disease while attending to patients. The last patient, who apparently had been infected by her husband during the convalescent period, was admitted in November 1967.²⁷⁶ Six cases (including two secondary infections) occurred in Frankfurt, Germany concomitant with the Marburg infections.³⁷² In September, two cases were identified in Belgrade, former Yugoslavia, in which a veterinarian was infected while performing a necropsy on a dead monkey and transmitted the virus to his wife, who nursed him early in his illness.²⁷⁶ A total of 31 cases (including six secondary infections) were identified, with seven fatalities in primary infections (23%). Subsequent serologic investigations have suggested that there was one additional primary case in Marburg.³⁷⁰

MHF remained an obscure medical curiosity until 1975, when three cases were reported in Johannesburg, South Africa.¹²² The index case was a white male who just prior to his infection had traveled in Zimbabwe. Seven days after onset, his travel companion also became ill and transmitted the disease to an attending nurse; the index case was the only fatality. An investigation was conducted along the travel route of the index case, but the source of the virus was not determined.⁶⁶ Two further episodes of MHF were reported from Kenya in 1980 and 1987. The index case in 1980 became ill in western Kenya and died in Nairobi, where an attending physician was infected but survived the disease.³⁷¹ In 1987, a fatal case occurred in the same region of western Kenya.²¹⁸ The 1980 and 1987 index cases both traveled to the Mt. Elgon region, which is located close to Lake Victoria and was the source of the monkeys that initiated the original 1967 outbreak (trapped near Lake Kyogo, Uganda).

The first outbreak of MHF in a community setting of central Africa started in October 1998 in Durba/Watsa, located in the northeastern region of the Democratic Republic of Congo (DRC). Its remote location and the hazards of an ongoing armed conflict hampered efforts to study this outbreak, but an investigation was initiated after the death of an attending physician in 1999. Sporadic cases continued and were directly or indirectly linked to activity in the vicinity of an underground gold mine. Primary cases were mainly gold miners who started multiple, usually short chains of human-to-human transmission within their families. Overall, 154 cases were reported with a case fatality rate (CFR) of 83%. Analysis of viral sequences derived from clinical specimens and virus isolates showed nucleotide diversity up to approximately 20%.^{22,23,65,400,401} The largest outbreak of MHF (252 cases with 227 deaths; CFR of 90%) took place in northern Angola, Uige province. The first cases date back to October/November 2004, but initial diagnostic tests were negative for filoviruses. The main outbreak started in February/March 2005 and the last confirmed case died in July. Initial infections were linked to a Uige hospital and included a high number of pediatric cases. Sequence analysis of virus isolates suggested a single introduction into the community.^{151,211,401} The latest MHF episode dates to 2007, with four documented cases associated with a single mine in western Uganda.⁴⁰⁰ In addition, two imported cases were reported from the United

States (nonlethal) and the Netherlands (lethal), who independently visited the same cave in Uganda in 2008.^{6,396}

Ebola Hemorrhagic Fever (EHF)

EHF was first reported in 1976, when EBOV appeared simultaneously in the DRC (at that time Zaire) and Sudan with 318 (CFR of 88%) and 284 cases (CFR of 53%), respectively. These epidemics were determined to have been caused by two distinct species (ZEBOV and SEBOV), a fact not recognized until years later. Viruses were isolated from patients of both outbreaks and named after a small river in northwestern DRC.^{36,449,450}

No index case was clearly identified in the Sudan outbreak in 1976, although initial cases originating in Nzara, Sudan, involved six cotton factory workers and their close relatives. The epidemic was augmented by the spread of cases to neighboring areas (Maridi, Tembura, and Juba). High levels of transmission occurred in the hospital of Maridi (a teaching center for student nurses), primarily through the use of contaminated needles and a lack of barrier nursing practices. At the same time, a larger outbreak in the DRC, centered around a Belgian mission hospital in Yambuku, Equateur Region, was being fueled by similar circumstances. During a 7-week period of the outbreak, the single most significant factor in the spread of infection in the hospital was the reuse of contaminated syringes and needles, although secondary transmission to family members caused 45% of all recorded infections. The outbreak ended with closure of the hospital and quarantining of infected patients.

In 1977, a single fatal ZEBOV case was reported from Tandala, DRC, about 325 km from the original focus of the 1976 Yambuku outbreak.¹⁷⁹ SEBOV reemerged in 1979 in Nzara and Yambio, Sudan. The index case worked in the same textile factory cited as the potential source of infection in the 1976 Sudan outbreak. Hospitalization of the patient led to four nosocomial infections and further transmission to five families (34 cases with 22 fatalities).⁴⁵¹

No further cases of EHF were reported until 1994, when a novel EBOV (ICEBOV [CIEBOV]) was isolated from an ethnologist who had become ill while working in the Tai Forest reserve of Ivory Coast. The infection was determined to have occurred while performing a necropsy on a dead chimpanzee (whose troop had lost several members to EHF).^{114,243} Later, a single seroconversion suggested a second nonfatal human case in nearby Liberia. This episode extended the geographic distribution of known EBOV cases to include most of the African rain forest and was the first case in West Africa.

In 1995, a strain of ZEBOV very similar to the original 1976 virus reemerged in the DRC, causing a large hospital and community outbreak of EHF in and around Kikwit.^{223,453} The presumed index case was a charcoal worker, but transmission escalated following two consecutive laparotomies performed on an infected male laboratory worker at Kikwit General Hospital. About three-quarters of the first 70 patients within the subsequent developing epidemic were health care workers. In total, there were 315 cases and 250 deaths (CFR of 81%). Major risk factors for contracting disease were involvement in patient care in hospitals and households and preparations of bodies for burial.

Beginning in 1994, ZEBOV became active in or adjacent to the central African rain forest on both sites of the border between Gabon and the Republic of Congo (RC).^{5,148} Almost all outbreaks in this region described in this section were associated with hunting and butchering of wildlife, often

great apes. The first epidemic was reported in 1994 from the Ogooué-Ivindo Province in northeast Gabon with a total of 52 cases (CFR of 60%).¹⁴⁷ In 1996, two more outbreaks were reported from the same province.¹⁴⁷ The first epidemic started in early February and included 37 cases (CFR of 57%); the second episode began in July/August and resulted in 60 cases (CFR of 75%). The latter epidemic included an imported case in South Africa where an ill Gabonese physician infected a nurse who died with EHF (2 cases; CFR of 50%). The first reported epidemic that crossed the border into the RC began in late November of 2001 with the index case again reported from Ogooué-Ivindo Province in northeast Gabon. The epidemic spread to Mekambo and Makokou and from there into the RC by ill Gabonese who sought medical care by traditional healers. In total, there were 65 (CFR of 82%) and 59 (75%) cases from Gabon and the RC, respectively.²⁵¹ The next occurrence of EHF was a large epidemic reported from the districts of Mbomo and Kelle in Cuvette Ouest Region, RC, in late 2002 to May 2003 with 143 cases (CFR of 90%), followed in late 2003 by a smaller episode in the district of Mbomo with 35 cases (CFR of 83%).¹¹⁵ A neighboring area (Etoumbi) was affected in 2005 by a small outbreak of EHF with 12 cases (CFR of 75%) (http://www.who.int/csr/don/2005_06_16/en/index.html) (Table 32.1). This has so far been the last reported outbreak in this region.

In 2000 to 2001, the largest known epidemic of filovirus disease occurred in Uganda, with 425 cases and 224 deaths. The causative agent was closely related to SEBOV from the Sudan 1976 and 1979 outbreaks, and marked the first appearance of EBOV in Uganda. The CFR of 53% was in line with the generally lower mortality associated with the SEBOV species.⁴⁵⁴ The epidemic was mainly concentrated in the Gulu district, a savannah area located in the north of the country close to the Sudanese border, with person-to-person transmission including nosocomial infections. The index case was never identified. During the epidemic, the virus spread to the neighboring Masindi district and more distantly to the town of Mbarara in southwestern Uganda.³¹ During this outbreak a high number of health care workers were infected after barrier nursing procedures were instituted. It was also the first time that laboratory diagnostics were performed in the field to assist in outbreak management.⁴⁵⁴ In 2004, southern Sudan was again affected by a small SEBOV outbreak with 17 cases, of which 7 died (CFR of 41%).⁴⁵⁵ The index case had butchered a monkey and human-to-human transmission was mainly by contact.

The last reported ZEBOV outbreaks occurred in the Kasai Occidental province of the DRC in 2007 and 2008/09. The first larger outbreak included 264 reported cases with a CFR of 71%⁴⁵⁷; the second smaller outbreak had 32 cases, of which 15 died (CFR of 47%).⁴⁵⁸ Both outbreaks affected rural communities in the vicinity of the city of Luebo and are thought to be related to hunting and handling of migratory fruit bats.²⁴⁸

A new EBOV species, designated *Bundibugyo ebolavirus* (BEBOV), has been identified as the causative agent for an outbreak that occurred in the Bundibugyo district in western Uganda in 2007.^{403,423} In total, there were 149 reported cases, with 37 deaths (CFR of 25%); of these, 56 cases were laboratory confirmed. This single outbreak had the lowest reported CFR among all EBOV that have caused outbreaks in central Africa so far.

Most recently, a single case of SEBOV has been reported from Central Uganda.⁷ No further cases have been reported.

EHF in Nonhuman Primates

In November 1989, an EBOV with low or no apparent pathogenicity for humans was recognized in a shipment of cynomolgus monkeys (*Macaca fascicularis*) housed at a quarantine facility in Reston, Virginia. These monkeys were imported from a single supplier in the Philippines, and an unusually high mortality was observed in animals during transportation and quarantine. Simian hemorrhagic fever virus was also circulating in the facility; efforts to culture this virus led to the detection of a new species of EBOV that was named *Reston ebolavirus* (REBOV).^{72,203} The actual origin of this novel EBOV was never determined. Resumption of importation of monkeys led to new outbreaks of monkey disease in the United States in 1990 and 1996³³⁶ and in Italy in 1992.⁴⁵² Subsequent investigations have traced all shipments except one to a single supplier in the Philippines. The mode of contamination of this exporter's holding compound has never been ascertained, but whether the virus persisted in the facility or was reintroduced from wild-caught animals, the result was a continued movement of infected macaques. A few infected handlers were also identified by serologic methods without reports of severe illness or suspicious deaths among this cohort.²⁸⁵ Improved shipping, housing, and quarantine regulations regarding importation of monkeys have been implemented to protect the United States from future episodes of EBOV introductions.⁷⁴ Recently, REBOV emerged in pigs in the Philippines.¹⁴ The pigs were co-infected with porcine respiratory and reproductive virus (PRRS) and the actual pathogenic potential of REBOV in pigs remains unclear. This discovery certainly raises issues for food production. Six workers from pig farms and slaughterhouses developed antibodies to REBOV, indicating that they became infected but did not develop disease. The potential for REBOV as a human pathogen remains unanswered but should not be totally dismissed. As of yet, REBOV infections/exposures have never resulted in clinical disease in humans.

Note, in 2012, Uganda has reported two EHF and one MHF outbreak; another EHF outbreak was reported from DRC. The EHF outbreaks were caused by SEBOV and BEBOV. The border region between Uganda and DRC seems to be the new "hot spot" for filovirus infections. For more information, please see the CDC and WHO websites.

Laboratory Infections/Exposures

A single laboratory infection of EHF occurred in the United Kingdom in 1976. Treatment with human leukocyte interferon and human convalescent plasma was initiated and the patient survived.⁸⁷ In the past two decades there have been at least three laboratory infections with MARV (1 fatal) in Russia.²⁸² In 2004, accidental ZEBOV exposures via needlesticks while working with animals occurred in the United States and Russia, but only the latter became infected (fatally).^{196,233} In 2009, a German researcher had an accidental ZEBOV exposure via needlestick while working with animals. The person was treated with a recombinant vesicular stomatitis virus (VSV)-based vaccine expressing the ZEBOV glycoprotein. It could not be determined if the exposure resulted in infection.¹⁵⁸

VIRION STRUCTURE

Initial electron microscopic (EM) observations of filoviruses revealed distinctive bacilliform to filamentous virus particles; it was this highly characteristic morphology that inspired their name (Latin *filum*, *thread*).^{294,316} The virions of MARV and EBOV produced in tissue culture are pleomorphic, appearing as either U-shaped, 6-shaped, or circular (torus) configurations, or as elongated filamentous forms of varying length (up to 14,000 nm), all from the same culture fluid (Figs. 32.1A–C). The filamentous forms can also be seen to form branched structures (Fig. 32.1C, *arrow*). The unit length associated with peak infectivity for MARV and EBOV was measured to be 860 and 1,200 nm, respectively.¹³⁹ Virions have a uniform diameter of 80 nm, contain a helical ribonucleoprotein complex or nucleocapsid (NC) roughly 50 nm in diameter (Figs. 32.1 and 32.2), and have a central axial space (~20 nm in diameter) running the length of the particle. The NC has a helical periodicity of ~5 nm (Fig. 32.1G), and is surrounded by a matrix protein and a closely apposed outer envelope derived from the host-cell plasma membrane. The virion surface is studded with membrane-anchored peplomers projecting ~10 nm from the surface (Figs. 32.1E and 32.1F). Virions can often appear ragged or “moth-eaten” (Fig. 32.1D) (especially late in the infection). The density of virions has been determined to be 1.14 g/mL by centrifugation in a potassium tartrate gradient.

GENOME STRUCTURE AND ORGANIZATION

The single-stranded, negative-sense RNA molecule that makes up a filovirus genome constitutes ~1% of the virion mass.³³⁰ The genomes of filoviruses are very similar in their organization, which generally conform to those of paramyxoviruses and rhabdoviruses, but their complexity is more akin to those of paramyxoviruses. Filovirus genomes are approximately 19,000 bases in length, making them the largest in the order *Mono-negavirales* (Fig. 32.2), and contain seven sequentially arranged genes in the order nucleoprotein (NP)–viral protein (VP) 35–VP40–glycoprotein (GP)–VP30–VP24–polymerase (L). Genes are delineated by conserved transcriptional signals, and begin close to the 3′ end of the genomic sequence with a start site and end with a stop (polyadenylation) site. For rhabdo- and paramyxoviruses, genes are usually separated by short intergenic regions of one or more nucleotides, which are also seen in filovirus genomes. An unusual feature of all filovirus genomes is the presence of gene overlaps, which have been identified in the genomes of some paramyxo- and rhabdoviruses, but do not resemble those of filoviruses. As seen in Figure 32.2, the stop site of an upstream (3′) gene overlaps the start of the downstream gene, and overlapping sequences are limited to the conserved transcriptional signals and are centered on a 3′-UAAUU pentanucleotide sequence common to start and stop sites.^{49,98,103,157,192,347} There is one overlap in the MARV genome (VP30–VP24), but the characterized EBOV genomes contain at least two overlaps (VP35–VP40, GP–VP30, and VP24–L; REBOV lacks the GP–VP30 overlap). Intergenic regions of filovirus genomes are generally short, although all genomes have a single lengthy sequence (>120 bases) separating the GP and VP30 genes of MARV and the VP30 and VP24 genes of EBOV. The positioning of the MARV overlap and a

long intergenic region (that precedes the VP30 gene) appears to be shifted one gene (in the 3′ direction) with respect to the genome of the EBOV. The significance of this arrangement and how it may have been generated are unknown. The extragenic sequences at the 3′ end of all filovirus genomes (leader) are short, ranging in length from 50 to 70 bases, while the length of the 5′ end (trailer) sequences are variable. The extreme 3′ and 5′ ends of the filovirus genomes are conserved, show a high degree of complementarity, and potentially form stem-loop structures.^{67,290,352,414} Filovirus trailer sequences are more variable in length, the longest being that of ZEBOV (677 bases), followed by BEBOV (475 bases), ICEBOV (474 bases), SEBOV (381 bases), MARV (76–95 bases), and REBOV (25 bases).

The evolutionary profile of the family *Filoviridae* (Fig. 32.3) indicates that EBOV and MARV represent distinct filovirus lineages, the five species of EBOV also represent distinct lineages, and there is an extraordinary level of genetic stasis within the lineages of EBOV. Nucleotide and amino acid differences between MARV and EBOV are both approximately 55%, whereas EBOV species show 32% to 41% differences in nucleotide and amino acid sequences.^{98,353,400} These same levels of sequence variation are also seen when other genes are compared. Within species of EBOV, however, there is a remarkable degree of genetic stability, indicating that these viruses have most likely reached a high degree of fitness as they have adapted to their respective niches. MARV isolates have not shown the degree of variation seen among EBOV species, but two lineages of MARV have been described that are genetically distinct by more than 20% genetic diversity.^{98,354,400}

VIRUS PROTEINS

Filovirus structural proteins can be subdivided into two categories, those that form the NC and those that are associated with the envelope (Fig. 32.2 and Table 32.2). The NC-associated proteins are involved in the transcription and replication of the genome, whereas the envelope-associated proteins have a role in either the assembly of the virion or virus entry. Shown in Figure 32.4 are the characteristic migration patterns of purified filovirus proteins separated by SDS-PAGE.

Nucleoproteins

The NP and VP30 proteins of filoviruses are the major and minor nucleoproteins, respectively, are phosphorylated, and interact strongly with the genomic RNA molecule to form the viral NC (along with VP35 and L).^{27,261} Expression of recombinant NP alone in mammalian cells results in the formation of inclusions and nonspecific association with cellular RNA to form helical structures.^{306,435} Analysis of NP amino acid sequences has identified a conserved, hydrophobic N-terminal half that contains all the cysteine residues, and a divergent, hydrophilic C-terminal half that contains most of the proline residues and is extremely acidic.^{348,349} The N-terminal 450 amino acids of the ZEBOV NP have been linked with self-assembly of NP into tube-like structures that may function as a platform for NC formation.⁴³⁵ Predicted mass values for NP molecules are approximately 20 kd smaller than estimated sizes derived from SDS-PAGE migration, possibly as a result of reduced binding of SDS molecules to the negatively charged NP. This hypothesis is supported by a study of recombinant

Shown are low magnifications of MARV (strain Angola 2005) (A), SEBOV (strain Yambio 2004) (B), and MARV (strain Yambio 2005) (C), and higher magnification images of ZEBOV (strain Mayinga 1976) (D, E), MARV (strain Ravn 1987) (F), and SEBOV (strain Yambio 2004) (G). Arrows indicate a branch point in a filamentous particle (C) and peplomers on the surface of virions (E, F). (Courtesy of A. Sanchez and C. Humphrey, Centers for Disease Control and Prevention, Atlanta, GA.)

FIGURE 32.2. Schematic representation of a filovirus particle (*top*) and the organization of filovirus genomes (*bottom*).

ZEBOV NP³⁶³ that mapped this property to two C-terminal domains (aa 439–492 and 589–739). In the central region of the NPs of filoviruses is a highly conserved region that shows some homology with nucleoprotein sequences of paramyxoviruses, and to a lesser extent rhabdoviruses, and likely has a similar structure and function.^{183,349}

The VP30 protein of ZEBOV is also capable of binding RNA, particularly a stem-loop structure located near the leader sequence; this property mapped to residues 26 to 40 that is arginine rich.²¹⁴ This region may have an additional role of binding to the acidic C-terminal half of NP. VP30 contains a zinc-finger motif ~70 to 80 residues from the N-terminus that is highly conserved in filoviruses (consensus = CX₈CX₄CX₃H X₂D/E),²⁸⁶ and RNA binding activity is increased by Zn²⁺.²¹⁴ Immediately C-terminal to this sequence (separated by six residues) is a conserved tetraleucine sequence linked to co-trans-

lational homo-oligomerization of VP30.¹⁶⁸ Additional studies have shown that the C-terminal half of VP30 also contains a homo-oligomerization domain and that hexamerization occurs via an N-terminal domain.¹⁶⁹ A functional study of recombinant ZEBOV VP30 has revealed that it behaves as a transcription activator^{169,440} regulated by its phosphorylation state,²⁸⁷ but this property appears to be absent from the VP30 of MARV.²⁸⁹ The ZEBOV VP30 also interacts with L; a role of bridging NP and L in the NC complex has been postulated.¹⁵⁴ Recently, the ZEBOV VP30 (along with VP35 and VP40) has been implicated in suppressing antiviral immunity through its antagonistic effect on the host cellular RNA interference (RNAi) pathway.⁹¹

Polymerase Complex Proteins

The L and VP35 proteins form the polymerase complex, which transcribes and replicates the filovirus genome. The

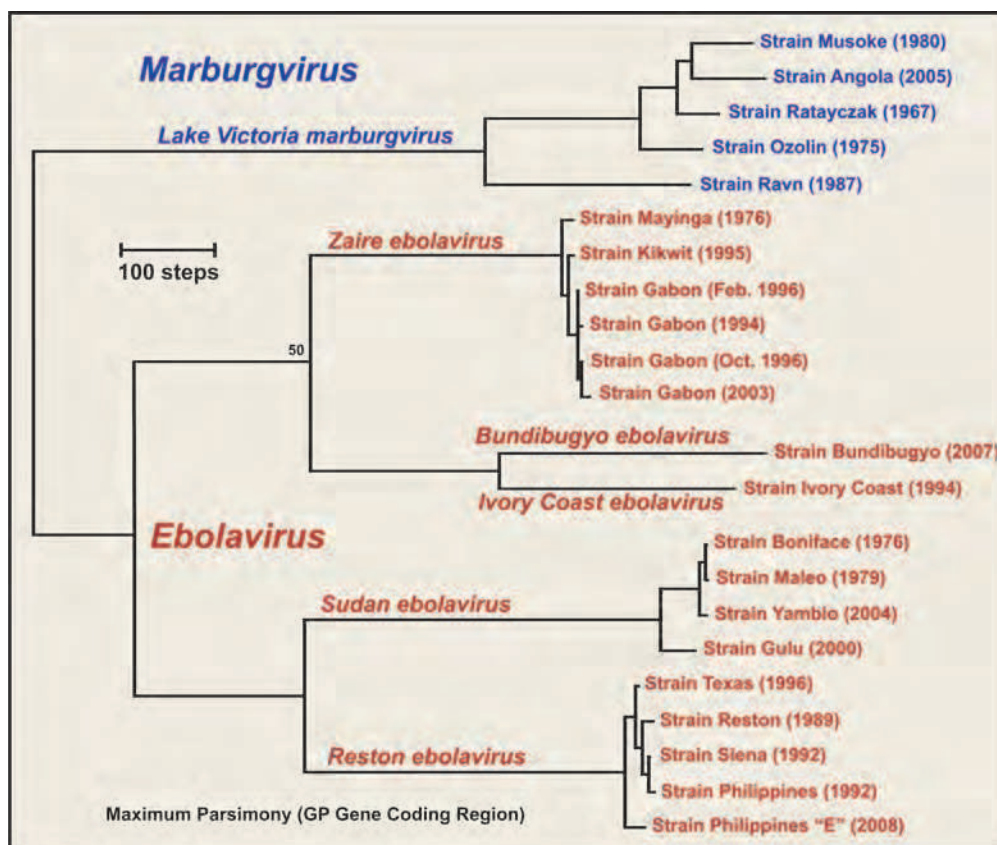

FIGURE 32.3. Phylogeny of the family Filoviridae. Nucleotide sequences for the GP gene coding region (ORF) of filovirus isolates were aligned using Clustal X version 2.0, and phylogenetic (maximum parsimony) analysis was performed using the MEGA5 computer program. Sequences were obtained from GenBank. The tree represents the most parsimonious tree, and confidence values at branch points were generated from 1,000 bootstrap replicates.

TABLE 32.2 Filovirus Genes and the Functions and Relative Molecular Weights of Their Gene Products

Gene order	Gene	Protein function	MW (kd) ^a
1	Nucleoprotein (NP)	Major nucleoprotein; RNA encapsidation	90–104
2	Virion protein (VP) 35	Polymerase complex cofactor; interferon antagonist	35
3	VP40	Matrix protein; virion assembly and budding; interferon antagonist ^e	35–40
4	Glycoprotein (GP)	Virus entry (surface peplomer); receptor binding and membrane fusion	150–170 ^b
	Soluble glycoprotein (sGP)	unknown	50–55 ^c
	Small soluble glycoprotein (ssGP)	unknown	50–55 ^c
5	VP30	Minor nucleoprotein; RNA encapsidation and transcription activation	27–30
6	VP24	Minor matrix protein; virion assembly; interferon antagonist ^d	24–25
7	Polymerase (L)	RNA-dependent RNA polymerase; enzymatic component of polymerase complex	~270

^aMolecular weights (MW) are approximated and based on SDS-PAGE migration.

^bMW is for the monomeric heterodimer.

^cExpressed only by EBOV; MW is for the monomeric form.

^dOnly shown for EBOV.

^eOnly shown for MARV.

FIGURE 32.4. Migration patterns of filovirus proteins separated by SDS-PAGE on a 10% acrylamide gel (stained with Coomassie blue). The far left lane contains highly purified ZEBOV sGP, while the other lanes contain proteins from purified virion preparations from various filovirus isolates. Approximate migration locations for EBOV and MARV proteins are shown at the left and right margins, respectively, and year of isolate/outbreak is shown along the bottom.

L protein provides the RNA-dependent RNA polymerase activity of the complex; motifs linked to RNA (template) binding, phosphodiester bonding (catalytic site), and a ribonucleotide triphosphate binding have been described.^{290,414} Conserved regions or “blocks” of sequences have been identified in filovirus L proteins, but there are also areas of divergence (particularly within the C-terminal quarter of the molecule) and sequences that are unique to the larger MARV L protein.

VP35 has an essential role as a cofactor that affects the mode of RNA synthesis (transcription or replication), similar to that of the P proteins of other NNS viruses^{290,292,321,415}; VP35 acts as a link between L and NP.²⁸ Basic residues in the C-terminal region have been identified as critical to viral RNA synthesis.³²¹ The ZEBOV VP35 has also been shown to be a virulence factor through its inhibitory effect on the host innate immune system.²⁵⁵ VP35 has an antagonistic effect on the interferon type I pathway (see Host Immune Response section) by binding virus-generated double-stranded RNA (dsRNA) and by directly interfering with pathway kinases^{19,20,21,54,90,170,171,253,322,323}; as noted previously, it also acts as a suppressor of RNA silencing.^{91,162} A C-terminal domain in VP35 confers its dsRNA binding property¹⁷¹ and X-ray crystallography studies of ZEBOV and REBOV VP35 have shown that it forms an asymmetrical dimer, the units of which separately bind and “end-cap” dsRNA^{226,253,254,255} (Fig. 32.5). Additionally, the ZEBOV VP35 interacts with the 8kDa dynein light chain, a component of the microtubule transport system,²³⁷ which may have an effect on the virus life cycle.

Structural (Surface) Glycoprotein

As noted earlier, the surface of the filovirus virion is covered with peplomers (spike structures) composed of the structural

glycoprotein, GP, and is anchored in the envelope in a type I orientation (Figs. 32.1 and 32.2). GP has been the most studied of the filovirus proteins, due in large part to its role in virus entry, its influence on pathogenesis, its antigenicity, and its attractiveness as an immunogen in vaccine development. The GP of EBOV species is encoded in two reading frames and expressed through transcriptional editing (^{353,410}; see Stages of Replication, next section), while the GP of MARV is encoded in a single ORF.^{49,103} Despite this difference, the features of their amino acid sequences are very similar. A schematic representation of the EBOV GP is depicted in Figure 32.6 and illustrates the general characteristics of a filovirus GP molecule.

The glycoproteins of filoviruses are translocated into the endoplasmic reticulum (ER) by a signal sequence at the N-terminus of GP₀ (precursor molecule) and are anchored by a membrane-spanning sequence at the C-terminus (Fig. 32.6); the cytoplasmic tail is extremely short (3 residues for EBOV and 7 for MARV). As GP₀ is transported through the ER and Golgi apparatus, it is glycosylated with both N-linked glycans (hybrid and complex) and O-linked glycans.^{104,107,149,409} An extremely divergent, mucin-like region (rich in threonine, serine, and proline residues) is located in the middle of GP₀ and is heavily glycosylated; all O-linked glycans are located in this region. Analysis of the carbohydrate composition of GP has shown that MARV isolates lack terminal sialic acid when grown in Vero E6 or MA-104 cells, unlike the GP of EBOV species, which contain abundant $\alpha(2-6)$ and/or $\alpha(2-3)$ linked sialic acids.^{104,149} Differences in sialic acid addition may be caused by differences in targeting as they are directed though the *trans*-Golgi apparatus. In addition, no neuraminidase activity has been found with any filovirus. The MARV GP (Musoke strain) is also phosphorylated by Golgi protein

FIGURE 32.5. Structural features of the ZEBOV GP, sGP, VP40, VP30, and VP35 molecules. The left panel shows schematic structures for GP and sGP. The basic features of GP are essentially the same for all filoviruses, as are those of sGP for all EBOV species. Structural depictions of the GP₂ trimer and the C-termini of VP40, VP30 (dimer), and VP35 (four molecules bound to dsRNA) were generated from Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank files (PDB ID = 2EBO, 1ES6, 2I8B, and 3L25, respectively; <http://www.rcsb.org/pdb>). Structures were rendered using Cn3D 4.1 (<http://www.ncib.nlm.nih.gov/Structure/CnED/cn3d.shtml>)

kinases, putatively at serine residues near the center of GP₁ (²⁶⁰SSDDEDLATSGSGS²⁷³)³⁵⁷ the C-terminal set of 3 serines is conserved in MARV.³⁵⁴ The implications of this processing are unknown, but could influence the trafficking of MARV GP.

GP₀ is cleaved by furin, a subtilisin/kexin-like convertase localized in the *trans* Golgi, or a furin-like endoprotease at a site just C-terminal to a long, variable, mucin-like region.^{356,413,417} Cleavage leads to the formation of a GP_{1,2} heterodimer that is held together by a single disulfide bond formed between the most N-terminal cysteine of GP₁ (cysteine at position 53 in ZEBOV) and the fifth cysteine from the N-terminus GP₂ (predicted) (Fig. 32.6). The MARV cleavage site is located ~70 residues N-terminal to that of the EBOV site, and a second conserved furin/furin-like cleavage sequence is located immediately after the second cysteine from the N-terminus of GP₂ (just within the first heptad repeat), but there is no evidence that this sequence is cleaved. It should be noted that cleavage of GP₀ to form the GP_{1,2} heterodimer is not required for virus entry in tissue culture, as mutation of the furin cleavage site does not prevent entry by pseudotyped virus,^{199,448} nor does it significantly affect infection and subsequent spread by a recom-

binant ZEBOV or virulence in nonhuman primates.^{301,302} Nevertheless, cleavage may be required for efficient maintenance in the natural host.

Peplomers are composed of trimerized GP_{1,2} heterodimers, and X-ray crystallography studies of a recombinant-expressed portion of GP₂ have shown that trimerization occurs when heptad repeat sequences form coiled coils in a rod-shaped structure (Figs. 32.5 and 32.6) similar to those of the HA₂ of influenza, the transmembrane (TM) of retroviruses, and SNAREs.^{269,442,443} Two conserved cysteine residues at the C-terminal end of the membrane spanning sequence are palmitoylated,^{119,200} which could stabilize the anchorage of the peplomer and may influence virus entry, although GP pseudotyping studies suggests that these cysteines are not essential for infectivity.^{200,209} The TM region of GP₂ has been linked to increased permeability of infected cells with the 667ALF669 sequence particularly important.¹⁶⁵ A fusion peptide is internally positioned near the N-terminus of GP₂ and is flanked by two conserved cysteines that are predicted to form a disulfide bond; this arrangement is very similar to the TM of Rous sarcoma virus and avian leukosis virus.^{120,209} The fusion peptide of ZEBOV inserts efficiently

FIGURE 32.6. Features of the GP (top), sGP (bottom left) and ssGP (bottom right) proteins of ZEBOV. N-linked glycosylation sites (Y) and cysteine residues (S) are identified along the sequences. The basic features of GP are essentially the same for all filoviruses, as are those of sGP and ssGP for all EBOV species.

into synthetic membranes containing phosphatidylinositol and promotes fusion of lipid vesicles.^{1,200,341,375}

Sequence analysis of the GP gene coding regions indicates that the N-terminal end (~200 residues) of GP₁ and most of GP₂ are conserved and have regions of increased hydrophobicity. The N-terminal region of EBOV GP₁ contains conserved cysteine residues that are closely positioned and form intramolecular disulfide bonds (C108–C135, C121–C147), which are also found in the sGP molecule^{15,209,418} and likely form an important structural feature. The MARV GP has conserved cysteines that correspond to the C108–C135 linkage of EBOV, but the other two closely positioned cysteines appear to be shifted towards the center of the molecule (and likely form a disulfide bridge). The abundant O-glycans of the mucin-like region confers an extended structure and its heavy glycosylation makes it very hydrophilic. The mucin-like region is located at the C-terminus of GP₁, and was predicted to project away from the virion membrane (toward the aqueous environment) with the N-terminal end (linked to GP₂) contributing to the stalk structure of the peplomer (Fig. 32.5). X-ray crystallography of GP₁ has verified this prediction.²⁴¹ In tissue culture, it has been shown that the ectodomain por-

tion of the ZEBOV peplomer is released from cells (separate from virions) through proteolytic cleavage by tumor necrosis factor α -converting enzyme (TACE; zinc-dependent metalloprotease) near the transmembrane anchor (residue D637 of ZEBOV).⁷⁸ GP can also be released into the medium as peplomers anchored in vesicles extruded from the plasma membrane.⁴¹⁶

Nonstructural Glycoproteins

The expression of a nonstructural soluble glycoprotein (sGP) as the primary product of the GP gene of EBOV is unusual and an important distinction from MARV.^{353,410} The N-terminal ~300 amino acids of sGP are identical to those of the structural GP, but the C-terminus is unique in sequence (Fig. 32.6). sGP is produced from a precursor molecule that is also cleaved by furin (or a furin-like endoprotease) near the C-terminus to release a short peptide that seems to contain exclusively O-linked glycans and has been named delta peptide.^{409,419} No biologic activity has been attributed to delta peptide. Biochemical and antigenic analyses of the ZEBOV sGP have shown that it is structurally distinct from GP^{15,356,418,419} and is secreted from infected cells as a homodimer that is likely formed in

the ER. Initial structural studies indicated an antiparallel orientation for sGP molecules in the dimer by disulfide bonding between cysteine residues C53 and C306.⁴¹⁸ However, subsequent MALDI-TOF MS analysis of sGP peptide fragments have unequivocally demonstrated a parallel orientation for the homodimer, which is held together by disulfide bonds between the N-terminal (C53–C53′) and C-terminal (C306–C306′) cysteines that fix the orientation of the molecules.^{15,95} The intramolecular disulfide bonds are similar in topology and spacing to the fibronectin type II module (binding site for collagen and gelatin), and may form a binding pocket for an as-of-yet unidentified ligand. Biophysical characterization of ZEBOV sGP has also revealed that the tryptophan residue at position 288 is C-mannosylated,^{16,94} an unusual form of glycosylation, at the specific motif W-X-X-W (first W is C-mannosylated) that is in the shared N-terminal region and is conserved in all EBOV species. GP₁ is presumed to have this same type of glycosylation. It is possible that sGP could contribute to disease progression, because large amounts circulate through the blood of acutely infected humans,³⁵⁰ but there has been no evidence linking sGP to a role in pathogenesis.

Recently, another ZEBOV nonstructural glycoprotein, termed small soluble glycoprotein (ssGP), has been identified and partially characterized,²⁸¹ and outwardly appears to be a truncated version of sGP. As with GP, ssGP is expressed through transcriptional editing. This glycoprotein is expressed at a low level (~1/20 that of sGP+GP) and has structural properties similar to that of sGP, in that it has N-linked glycans (no O-linked) and exists as a homodimer (disulfide bond between cysteines at position 53). As with sGP, the function of ssGP has yet to be adequately defined, but ssGP appears to lack an anti-inflammatory property reported for sGP.²⁸¹

Matrix Proteins

The VP40 protein functions as the matrix protein and the VP24 protein may have a secondary/minor matrix protein function.¹⁶⁴ VP40 is the most abundant protein in the virion, while only small amounts of VP24 are incorporated into virus particles (Fig. 32.4). Both proteins have an affinity for membranes and are associated with the virion envelope (no membrane-spanning regions),^{208,340,362} and are easily released from virions by nonionic detergents under low-salt conditions.^{85,225} VP40 is critical to the budding process, as it initiates and drives the envelopment of the NC by the plasma membrane.²⁰⁷ In addition, it has been reported that both VP40 and VP24 of EBOV contribute to regulation of genome replication and transcription.¹⁸⁰

VP24 has a decidedly hydrophobic profile, and a study of a recombinant-expressed form (ZEBOV) indicates that it has an affinity for the plasma membrane and perinuclear region of infected cells.¹⁶⁴ VP24 is capable of forming homotetramers, which is influenced by pH and divalent cation changes. Because disulfide-bonded oligomers of VP24 are not evident in the virion,³⁵² the formation of multimers is likely due to ionic and/or hydrophobic interactions. The precise role of VP24 in the replication of filoviruses is still unclear and direct interactions with other virus proteins have not been described, but a role in formation of nucleocapsid-like structures has been described.¹⁶⁴ The VP24 of EBOV has also been reported to antagonize the interferon type I signalling pathway, similar to that of VP35 (see Host Immune Response section).²⁰

STAGES OF REPLICATION

Recent studies have provided valuable insights into filovirus entry into host cells and the mechanisms leading to the production and release of infectious progeny. Although very much incomplete, the details of this complicated series of molecular events are slowly being revealed. The current understanding of this process is illustrated in Figure 32.7 and described in the following sections.

Mechanism of Attachment

In filovirus infections a variety of host organs and cell types are involved; this broad tropism is related in large part to the binding properties of the peplomers that populate the surface of the virion. Because GP is the only filovirus protein involved in initiating infection, it has been intensely studied for its ability to bind cellular receptors. Much of the work directed at receptor binding (and subsequent entry processes) has utilized recombinant pseudotyping systems, which provide a safer and easier approach to characterizing these properties and events.^{56,58,200,390,447,448,467} However, these results need to be verified using infectious filoviruses, as interactions of GP with VP24 and/or VP40 need to be considered along with other properties that may be peculiar to filovirus virions.

Identification of attachment molecules (receptors?) involved in filovirus entry is complicated by the ability of GP trimers to specifically or nonspecifically bind a variety of host-cell surface molecules. The asialoglycoprotein receptor found on hepatocytes binds MARV,²⁹ yet EBOV also infects hepatocytes despite its GP having sialylated glycans. The β 1 group of integrins has been suggested to interact with ZEBOV GP on the cell surface and during intracellular trafficking (when co-expressed),³⁹³ although cells that express this molecule (such as Jurkat cells) are not easily infectible. The folate receptor alpha has been implicated as a cofactor in filovirus entry,⁵⁶ but virus entry independent of this molecule has been shown to take place.^{366,369} C-type lectins (DC-SIGN and DC-SIGNR; bind oligosaccharide ligands)—present on certain forms of dendritic cells, macrophages, and endothelial cells—are also capable of binding filovirus peplomers,^{3,12,279,365} especially when N-linked glycans contain high mannose carbohydrates.^{213,258} However, there are indications that DC-SIGN may not act as an EBOV receptor, but instead acts to promote attachment and other host factors are involved in entry.²⁸⁰ One study has shown that macrophages are more susceptible to virus entry by ZEBOV GP-pseudotyped HIV-1 particles than are monocytes, and that HUVEC cultures pretreated with TNF- α showed increased entry over untreated cells.⁴⁶⁷ These results imply that changes in cellular gene expression can alter the makeup of surface attachment molecules (and cofactors?). Antibody binding to peplomers might also enhance infectivity through its interaction with the Fc portion of the complement protein C1q bound to the surface of host cells.³⁹¹ Very recently, T-cell Ig and mucin domain 1 (TIM-1) has been described as a potential binding protein for EBOV GP and enhances virus entry into cells.²³²

Results of site-directed mutagenesis studies of ZEBOV GP have shown that individual glycosylation sites are not critical to virus entry,^{209,270} and deletion of the entire mucin-like region can actually increase virus entry *in vitro*.²⁰⁹ A role in receptor binding or increased binding has yet to be attributed to the mucin-like region. Further deletion of the GP₁ C-terminal

FIGURE 32.7. Schematic view of the processes associated with filovirus entry, synthesis of viral molecules, and the production of infectious virions in a susceptible eukaryotic cell.

sequences (past the mucin-like region), together with mutagenesis of N-terminal residues, has localized the entry function to ~150 residues at the N-terminus (residues 33–185).²⁷⁰ It should be noted that this region also contains the same intramolecular disulfide bonds as sGP, which potentially forms a binding pocket that is involved in cell attachment and/or receptor binding. If this is the case, then the corresponding region of MARV GP₁ would likely have distinctive binding characteristics due to a differing disulfide bonding pattern. In contrast, another study identified approximately the same region as the potential receptor binding site for both viruses, indicating that EBOV and MARV utilize a common receptor.²³⁹

Mechanism of Entry and Intracellular Trafficking

Following attachment, virions are presumed to enter the cell by a process of endocytosis, acidification of the endocytic vesicle, and fusion of virus and host membranes resulting in the release of the NC into the cytoplasm. ZEBOV GP-mediated entry and fusion are affected by the treatment of host cells with agents that disrupt microtubules or inhibit the function

of microfilaments.⁴⁶⁷ These cytoskeletal components are key to clathrin-dependent and caveolae-mediated internalization, and support the theory that filoviruses enter the cell through endocytosis. However, studies examining the type of endocytic pathway utilized by filoviruses are conflicting. One study has demonstrated that disruption of the caveola vesicular system (via cholesterol binding compounds) inhibited ZEBOV and MARV entry and that filovirus GP-pseudotyped virus co-localized with the caveolin-1 (cholesterol binding protein) marker.⁸⁸ However, cells lacking caveolae are infectible and co-expression of folate receptor alpha and caveolin-1 in a T-cell line did not increase infectivity.³⁶⁶ Clathrin-mediated endocytosis and GP-dependent macropinocytosis or a macropinocytosis-like mechanism for EBOV internalization and an involvement of lipid rafts.^{2,298,344} It should be noted that inhibitors of macropinocytosis (amiloride) and the lipid raft-caveolae endocytosis pathway did not significantly affect ZEBOV entry.³⁴⁵ Latest, it was reported that EBOV entry was dependent on Niemann-Pick C1 (NPC1), a protein known to function in cholesterol transport.⁵³ It thus appears that the entry of ZEBOV (and possibly other filoviruses) occurs through multiple routes.

A filovirus virion internalized in a vesicle at the plasma membrane traffics through the endosomal pathway, and at some point in time the NC is released into the cytoplasm by GP₂-mediated fusion of the virus envelope and endosomal membrane. Membrane fusion is dependent on endosomal acidification,^{392,447} and endosomal proteolysis of the GP₁ subunit peplomer by the cysteine proteases CatL and CatB (active in acidic pH environments) can enhance ZEBOV entry.^{44,59,222,345} CatL removes the glycan cap and mucin-like domain, exposing core residues of a recombinant peplomer and increasing infectivity.^{182,222} Removal of GP₁ is believed to set off a conformational change in the GP₂ trimer that triggers the deployment of the fusion machinery, resulting in the insertion of the GP₂ fusion peptides into the endosomal membrane. This event would link and draw viral and host membranes together to induce fusion and the release of the NC into the cytoplasm.⁴³⁶ The minimum number of peplomers needed to induce fusion has not been determined.

Transcription and Translation

Following filovirus entry, negative-strand RNA genetics dictates that transcription is the first (and obligatory) viral process, similar to paramyxoviruses and rhabdoviruses. Once the nucleocapsid is released into the cytoplasm, polyadenylated monocistronic messenger RNAs (mRNAs) are synthesized from virus genes in a 3' to 5' direction (with polar attenuation) from the encapsidated genomic RNA template. Transcription seems to involve a process of starting and stopping as the polymerase complex encounters conserved start (initiation) and stop (termination/polyadenylation) sites along the genome. Synthesis of the "leader" sequence is postulated to occur, but intergenic sequences and the "trailer" sequence seem to be ignored, although this has not been shown experimentally. NP mRNA can be detected as early as 7 hours postinfection, and peaks around 18 hours.³⁴⁶ It is assumed that transcripts are capped at the 5' end (⁷MeG⁵-ppp⁵-R) by the L protein, as it contains conserved motifs associated with this enzymatic activity.¹⁰⁸

Analyses of defective interfering particles of ZEBOV have shown that promoters for initiating RNA synthesis are contained within 156 and 177 nucleotide regions of the genomic and antigenomic RNA 3' termini, respectively.⁵² Subsequent to these studies, it was shown that a bipartite promoter is located within the first 128 nucleotides of the 3' end of the ZEBOV genome.⁴⁴¹ One element is located at the extreme 3' end and the other within the nontranslated region of the NP gene. These elements are separated by a nonspecific sequence (nucleotides 56–80) that acts to provide proper spacing and also contains the NP gene transcription start site. This bipartite promoter is similar to that of various paramyxoviruses (i.e., Sendai virus) and obeys the "rule of 6".⁴⁴¹

Transcriptional start sites are 12 or 14 nucleotides in length and end in the consensus sequence 3'-CUUCUAAUU for EBOV and 3'-CUURUAAUU for MARV, while stop sites are 11 or 12 nucleotides long with the conserved sequence 3'-UAAUUC(U)_{5/6}. Polyadenylation is believed to occur by slippage or stuttering of the polymerase at the 5 to 6 uridines ending the stop site. A characteristic that is unique to the transcriptional signals of filoviruses is a common pentanucleotide sequence, 3'-UAAUU, present at the 5' end of start sites and at the 3' end of stop sites¹⁰³; the stop sites of ZEBOV and

REBOV polymerase genes deviate slightly from this sequence (3'-UAAUA).

The mechanism initiating transcription of a downstream (5') gene involved in a gene overlap and the consequences of this arrangement are unknown. Because the overlaps are short (18–21 nucleotides), the proximity of the polymerase may not affect recognition of the start site as it finishes polyadenylating the upstream gene. The function of these overlaps remains unclear, but attenuation of transcription does not appear to take place, as the transcription of the VP40 and VP30 genes of ZEBOV is substantial and expression of VP40 is very strong.

Filovirus mRNA molecules have characteristics that make them somewhat unique. They contain long noncoding regions at their 3' and/or 5' ends, which contribute to the increased length of the genome and may function in the stability of transcripts. In addition, the 5' ends of filovirus transcripts have the potential to form stable, stem-loop structures, which might affect their stability and ribosome binding capacity/translation.^{291,347,352}

The ZEBOV VP30 has a transcription activation property that is linked to an RNA secondary structure formed at the 5' end of the NP gene transcript as it is synthesized^{168,169,286}; the presence of VP30 is required for transcription of downstream genes. This property is impaired by phosphorylation at six serines and one threonine at the N-terminus, and restored by the action of cellular phosphatases.²⁸⁶ Because ZEBOV VP30 in the virion is at least partly phosphorylated,⁸⁵ the action of phosphatases on the NC may be required before transcription proceeds efficiently. Thus, the phosphorylation state of VP30 may be a critical component in regulating EBOV RNA synthesis; a corresponding mechanism has not been shown for MARV.

The organization and transcription of the GP genes of EBOV are unusual and provide an important distinction between MARV and EBOV. The MARV GP gene encodes a single product, GP, in a conventional open reading frame (ORF), whereas all EBOV species encode their GP in two ORFs (-0 and -1 frames). Expression of the EBOV GP requires a transcriptional editing event^{281,353,410} comparable to the editing described for the phosphoprotein gene of certain paramyxoviruses. Translation of the unedited transcript of the EBOV GP gene results in the production of sGP, a smaller, nonstructural, secreted glycoprotein, the primary gene product (Figs. 32.4 and 32.6). The transcriptional editing event that leads to GP expression occurs at a series of seven uridines on the genomic RNA template and results in the insertion of an additional adenosine, which connects the GP open coding frames; approximately 20% to 25% of the transcripts are edited. The mechanism of insertion most likely evolved out of the polymerase's ability to polyadenylate by stuttering on a poly(U) template. However, insertion of a single nucleotide at the editing site appears to occur with a high degree of fidelity, but insertion of two adenines can occur (in ~5% of GP gene transcripts), which leads to the synthesis of low levels of ssGP.²⁸¹ The editing of EBOV GP gene transcripts is the only example of a virus glycoprotein that is expressed through this type of mechanism. Sequence analysis of the GP genes of MARV isolates indicates that a nucleotide sequence that corresponds to the editing region of EBOV GP genes is totally absent.^{49,103,356,445} The difference in filovirus GP gene

organization provides important evidence pointing to a divergent evolution for EBOV and MARV.

Replication of Genomic Nucleic Acid

In addition to transcription, the promoter at the 3' end of the genomic RNA also drives the synthesis of full-length complementary/antigenomic RNA from the encapsidated template. As with other NNS RNA viruses, the ends of the genome have a high degree of sequence complementarity,^{67,352} and stem-loop structures are predicted to form at the 3' and 5' ends of genomic and antigenomic RNAs. These structures are believed to be essential to the replication of filoviruses.⁶⁷ The initial expression of virus genes leads to a buildup of viral proteins (especially NP), which is thought to trigger a switch from transcription to replication. This switch results in the synthesis and encapsidation of antigenomic RNA molecules, which in turn serve as templates for genomic RNA that is also rapidly encapsidated. Depletion of capsid proteins is believed to cause a return to transcription, and eventually an equilibrium is established wherein transcription and replication are concurrent processes. As replication progresses in the infected cell, NC particles containing genomic RNA accumulate and are directed to the plasma membrane for virion assembly.

The development of reverse genetics systems based on EBOV and MARV genetics has provided significant advances in understanding filovirus replication^{32,89,156,289,292,301,395,415} and has allowed the production/reconstitution of recombinant ZEBOV and MARV (Musoke strain) from plasmid DNA.^{89,301,415} For MARV, the NP, VP35, and L proteins are all that is required to transcribe and replicate minigenomes,²⁹⁸ but systems developed for ZEBOV also required VP30.^{301,395,415} When components of minigenome reporter gene systems for REBOV and ZEBOV were switched, it was noted that *cis*-acting signals and nearly all combinations of proteins were exchangeable.³² Rescue of recombinant ZEBOV using NC-associated proteins from REBOV or MARV has also shown that exchanging of these heterologous proteins can lead to recovery of recombinant virus.³⁹⁵

Assembly and Release

When sufficient levels of negative-sense nucleocapsids and envelope-associated proteins are reached, a coalescing of these components occurs at the plasma membrane,²⁰⁷ or to a lesser extent at membranes forming intracellular vacuoles.⁹⁶ Filovirus-infected cells develop prominent inclusion bodies, easily visualized by light, immunofluorescent, and electron microscopy.^{183,294} Inclusions are induced by NP, but also contain other proteins that form the NC.²⁸ Inclusions may be a source of components for forming NCs, which can be seen associated with inclusions (Fig. 32.8A). Recombinant-derived, NC-like structures form in cells expressing NP, which may be facilitated by the expression of VP35 and VP24.^{183,305} NC particles are believed to interact with VP40 molecules in the budding process.

Membrane/lipid rafts have been identified as platforms for the assembly of filovirus virions.^{24,310} Membrane rafts are rigid microdomains (containing sphingolipids and cholesterol) present in biological membranes and are isolated from the fluid phospholipids surrounding them. GP trimers conveyed to the plasma membrane have an affinity for these lipid rafts, which is associated with palmitoylation of the membrane-spanning anchor sequence.²⁴

Structural and functional studies of VP40 have provided important insights into the assembly of filovirus virions.^{75,173,198,207,229,230,257,461} Posttranslational processing and intracellular trafficking of VP40 result in the deposition of VP40 at the plasma membrane via the vacuolar protein sorting/endosomal pathway. By itself, ZEBOV VP40 is capable of mediating its own release from mammalian cells to form enveloped virus-like particles (VLPs),^{208,256,307,399} which are more efficiently produced when GP and NP are present²⁵⁶; VP40 interacts with the C-terminal 50 amino acids of NP.²⁵⁷ ZEBOV VP40 determines VLP morphology and density,²¹⁹ and likely has the same influence on infectious filovirus particles. A structural study of ZEBOV VP40 demonstrated that it associates with lipid bilayers containing a high level of L- α -phosphatidyl-L-serine (abolished by 1 M NaCl).³⁴⁰ It was also found that this property maps to the C-terminal ~110 residues, which contains basic and hydrophobic regions that could bind membranes.³⁹⁷ In addition, the N-terminal region is involved in oligomerization, and deletion of the C-terminal region of VP40 allowed it to hexamerize into ring structures. The crystal structure of monomeric ZEBOV VP40 is composed of similar/related β sandwich domains (N-terminal and C-terminal) connected by a hinge region, which unfolds upon interaction with membranes and dimerizes in an antiparallel orientation (Fig. 32.5).³⁶² These dimers form octomeric rings (~84 Å diameter) with a central pore and RNA binding properties¹⁵² that may be essential for replication.¹⁸¹ Late (L) domain motifs are positioned near the N-terminus of filovirus VP40 molecules, and are important in posttranslational processing and tracking events that facilitate virus budding.^{173,405} The VP40 of EBOV contains overlapping PT/SAP and PPXY motifs (PTAPPE/AY), while MARV contains only the PPXY motif (PPPY). These L domain motifs on the ZEBOV VP40 interact with cellular proteins (with WW domains) associated with the endocytic pathway of mammalian cells^{229,230,257,272,398,465}; for ZEBOV the PPXY domain appears to have a greater role in budding efficiencies.³⁰⁰ Results of *in vitro* studies have suggested that VP40 is bound as an oligomeric form at its PPXY motif by Nedd4 and ubiquitinated, is subsequently targeted to endosomes or multivesicular bodies (MVB) by Tsg101 and VPS-4 (components of the vacuole sorting pathway), and is recruited to membrane rafts through Tsg101 interactions with VP40 and raft proteins (Fig. 32.7). The finding that small interfering RNA (siRNA)-silencing of Rab9, an enzyme important in late endosome transport, inhibits filovirus replication in Vero cells,^{60,297} as well as the observation that Rab11 is incorporated into MARV virions,²³¹ support the involvement of the endosomal sorting machinery in filovirus assembly. However, the details of VP40 transport from the late endosome to the plasma membrane have not been defined. In addition, mutation of L domains from VP40 did not prevent recovery of a recombinant ZEBOV, nor did it significantly reduce virus production in cell culture.³⁰⁰ This information suggests that VP40 can be transported to the plasma membrane through a process separate from endosomal trafficking. Raft-associated VP40 is believed to associate with NCs, drawing them tightly to the membrane where they are enveloped and extruded from the host cell as infectious virions (Figs. 32.7 and 32.8). Electron tomography studies of MARV budding indicate that the entire length of nucleocapsids associate laterally with the plasma membrane (much like a rising submarine), which is followed by its protrusion and release of

FIGURE 32.8. Transmission (A) and scanning (B) electron microscopy of Vero E6 cells infected with MARV (Angola 2005) and ZEBOV (1976), respectively. **A:** Low and higher magnification images of different cells with virus particles forming at and detaching from the plasma membrane (dark and white arrows, respectively). An inclusion body is marked with an asterisk and areas of nucleocapsid (NC) accumulation are identified. (A courtesy of A. Sanchez and C. Humphrey, Centers for Disease Control and Prevention, Atlanta, GA.) **B:** A multitude of filovirus particles (with varying lengths) are seen attached to and budding from the cell surface. the mature virion particle by being pinched off at the trailing end.^{405,444}

Effects on Host Cell Cultures

The growth of adapted strains of MARV and EBOV in cultured cells can be striking. Intracytoplasmic vesiculation and mitochondrial swelling are followed by a breakdown of organelles and terminal cytoplasmic rarification or condensation. In African green monkey kidney cell lines infected with filoviruses, cytopathic effects (CPE) are evidenced by a rounding and detachment of cells (without syncytia formation), which can result in a total loss of the monolayer (~5 days). However, replication of REBOV and ICEBOV is slow in tissue culture, and CPE is usually less evident and gener-

ally does not develop until after 7 to 9 days incubation. Persistent REBOV infection with continued production of large amounts of virus particles can be established in Vero E6 cells (A. Sanchez, unpublished observations) and ZEBOV can establish persistent infection under partial immunity.¹⁶¹ Filovirus infection does not lead to the shutdown of host-cell protein synthesis, but expression levels diminish as the infection progresses and virus proteins accumulate. The expression of GP has a cytotoxic effect that is associated with the mucin-like region.^{117,415,463} Elevated expression would likely impact the function of host-cell adhesion proteins by downregulating and/or displacing them,^{367,380,393} and could also cause cell detachment without cell death through a phosphorylation-dependent signal cascade.⁵⁷ Using a reverse genetics system,

it was further demonstrated that cytotoxicity depends on the level of GP expression, with overexpression leading to an early detachment and cytotoxicity of infected cells.⁴¹⁵ The effects of filovirus infections on endothelial cells and immunocompetent cells will be discussed in the next section.

PATHOLOGY AND PATHOGENESIS

Clinical investigations from episodes and outbreaks of human EBOV and MARV infections have provided important descriptive information on the pathology and pathogenesis of these agents; however, the available data are sparse, often fragmentary and sometimes paradoxical. Comprehensive studies have been carried out to a much greater extent in laboratory animals. Rodents—including guinea pigs, mice, and hamsters—have been employed to study viral hemorrhagic fever (VHF) caused by filoviruses.^{26,38,343,428,472} Because filovirus isolates derived from primates do not typically produce severe disease in rodents upon initial exposure, serial adaptation is required to produce a uniformly lethal infection. Mice and guinea pigs have served well as early screens for evaluating antiviral drugs and candidate vaccines, and genetically engineered mice clearly have utility for dissecting out specific host–pathogen interactions. However, the disease pathogenesis in rodent models is far less faithful in portraying the human condition than disease observed in nonhuman primates.^{40,143} As data derived from studies using rodents may not correlate with human disease or may be deficient in identifying certain processes, this section primarily focuses on data obtained from human clinical studies and experimental infections of nonhuman primates (Fig. 32.9).

Entry into Host

Little is known regarding what constitutes a typical dose and route of exposure in human filovirus infections. Viruses enter the host through mucosal surfaces, breaks or abrasions in the skin, or by parenteral introduction. While a recent study has suggested that exposure to fruit bats may have initiated a ZEBOV outbreak in the DRC in 2007,²⁴⁸ most cases that propagate outbreaks are thought to occur by direct contact with infected patients or cadavers.^{79,223,449,450} Infectious filoviruses and/or RNA have been isolated from semen and genital secretions^{275,333,338} and detected in skin in human cases⁴⁷⁰; they have also been demonstrated in skin, body fluids, and nasal secretions of nonhuman primates.^{137,205,368}

Laboratory exposure through needlestick and filovirus-infected blood has been reported.^{87,196} Reuse of contaminated needles played an important role in the 1976 EBOV outbreaks in Sudan and Zaire,^{449,450} and the question of whether reuse of contaminated needles contributed to some of the cases in the 2004 to 2005 outbreak of MARV in Angola was raised.⁴⁵⁶ A needlestick exposure involving an acute-phase patient would likely entail a dose of 1,000 plaque-forming units (pfu) or more if viremias associated with terminal patients are comparable to viremias in infected nonhuman primates, which often reach levels as high as 10^7 to 10^8 pfu/mL of serum.^{83,126,127,137,174,204,220,328} The generation of human viremia data has been notoriously problematic,²³⁵ but levels are thought to exceed 10^6 pfu/mL of serum in outbreaks of SEBOV and ZEBOV.^{402,450} The fact that circulating EBOV and MARV particles are readily observed by direct electron microscopic inspection of postmortem fluids and tissues^{76,86,138,294,468}

supports this view, considering that the lower limit for ultrastructural detection of virus particles is generally on the order of 10^6 pfu/mL of fluid or gram of tissue.

Butchering of a chimpanzee for food was linked to outbreaks of ZEBOV in Gabon¹⁴⁸ with contact exposure the likely route of transmission. While proper cooking of foods should inactivate infectious filoviruses, ingestion of contaminated foods cannot completely be ruled out as a possible route of exposure in natural infections. Organ infectivity titers in filovirus-infected nonhuman primates are frequently in the 10^7 to 10^9 pfu/g range^{126,127,137,174,204,220}; thus, it is likely that exposure through the oral route would invariably be associated with very high infectious doses. In fact, ZEBOV is highly lethal when orally administered to rhesus macaques.²⁰¹

The role of aerogenic transmission in outbreaks is unknown, but is thought to be rare.³¹⁵ Aerosol transmission in nonhuman primates was inferred in the 1989 to 1990 epizootic of REBOV,²⁰⁵ although it is thought that aerosols may have been created mechanically by workers cleaning the facility. High concentrations of REBOV in nasal secretions and ultrastructural detection of large numbers of viral particles in alveoli were reported.²⁰⁵ Filoviruses are reasonably stable in aerosols,^{25,61} and reports of interage transmission of ZEBOV and MARV between monkeys^{202,319,368} suggest that virus spread was mediated by small-particle aerosols. Moreover, ZEBOV and SEBOV are highly infectious by aerosol exposure in cynomolgus^{126,320,328} and rhesus^{217,328} macaques and African green monkeys,³²⁸ as is MARV in cynomolgus and rhesus macaques^{4,126,264} and African green monkeys.²⁵ Rhesus macaques were also lethally infected with ZEBOV by conjunctival exposure.²⁰¹

Host-Cell Pathology

The pathologic changes seen in patients dying with all filovirus infections seem similar, with extensive necrosis in parenchymal cells of many organs, including liver, spleen, kidney, and gonads; little inflammation is seen within infected tissues.^{76,294,295,468} The most characteristic histopathologic features are seen in the liver (Fig. 32.10), where hepatocellular necrosis is widespread with intact, hyalinized, ghost-like cells often remaining in place amid large amounts of karyorrhectic debris. Often, extraordinary numbers of virions are present in this debris. Characteristic intracytoplasmic inclusion bodies are present in intact hepatocytes. Light microscopic, electron microscopic, immunohistochemistry (IHC), and *in situ* hybridization studies show concordance between tissue damage, the presence of viral antigens and nucleic acid, and sites of virus replication, suggesting that direct viral damage is one major element in the pathogenesis of the disease (Figs. 32.9 and 32.10).

EBOV and MARV have a broad cell tropism, infecting a wide variety of cell types. IHC and *in situ* hybridization analyses of tissues from fatal human cases or experimentally infected nonhuman primates show that monocytes, macrophages, dendritic cells, endothelial cells, fibroblasts, hepatocytes, adrenal cortical cells, and several types of epithelial cells all support replication of these viruses.^{4,18,73,127,137,138,141,146,174,201,296,342,468,470} The sequence of infection, however, has not been fully elucidated. Temporal studies in nonhuman primates experimentally infected with either ZEBOV or MARV suggest that monocytes, macrophages, and dendritic cells are early and preferred replication sites of these viruses.^{137,174} These cells appear to play pivotal roles in dissemination of the virus as it spreads

FIGURE 32.9. Model of filovirus pathogenesis in primates. Monocytes, tissue macrophages, and dendritic cells appear to be early and preferred sites of filovirus replication. Soluble factors released from virus-infected mononuclear cells act locally and systemically. Release of chemokines from these virus-infected cells recruits additional monocytes and macrophages to sites of infection, making more target cells available for viral exploitation and further amplifying an already dysregulated host response. In addition, these soluble factors contribute to the impairment of the vascular system. Although filoviruses do not productively infect lymphocytes, the rapid loss of lymphocytes by the process of apoptosis is a noted feature of disease. This lymphocyte loss is probably due to a combination of factors including virus-induced impairment of dendritic cell function, release of proapoptotic soluble factors from virus-infected monocytes and macrophages, and possibly direct interaction between viral antigens and lymphocytes. Coagulation abnormalities are consistent features of filovirus disease and are caused by a number of factors, particularly during the later stages of disease; recent data strongly implicate a role for tissue factor. The hemodynamic and coagulation disorders are exacerbated by infection of hepatocytes and adrenal cortical cells, resulting in impairment in the synthesis of important clotting factors. At the same time, impaired secretion of steroid-synthesizing enzymes by virus-infected adrenal cortical cells leads to hypotension. DC, dendritic cell; NO, nitric oxide. (Adapted from a prior publication by Bray M, Geisbert TW. Ebola virus: the role of macrophages and dendritic cells in the pathogenesis of Ebola hemorrhagic fever. *Int J Biochem Cell Biol* 2005;37:1560–1566.)

from the initial infection site via monocytes/macrophages and dendritic cells to regional lymph nodes, likely by way of lymphatics, and to the liver and spleen through blood. At these locations, filoviruses infect resident macrophages and dendritic cells. Several lines of evidence suggest that filovirus-infected monocytes/macrophages release various soluble factors that

then recruit additional monocytes/macrophages to areas of infection; this makes more target cells available for viral exploitation, further amplifying the infection.^{39,137,174}

In addition to the macrophage-rich lymphoid tissues such as spleen, the liver and adrenal gland also appear to be important target organs for both EBOV and MARV; this

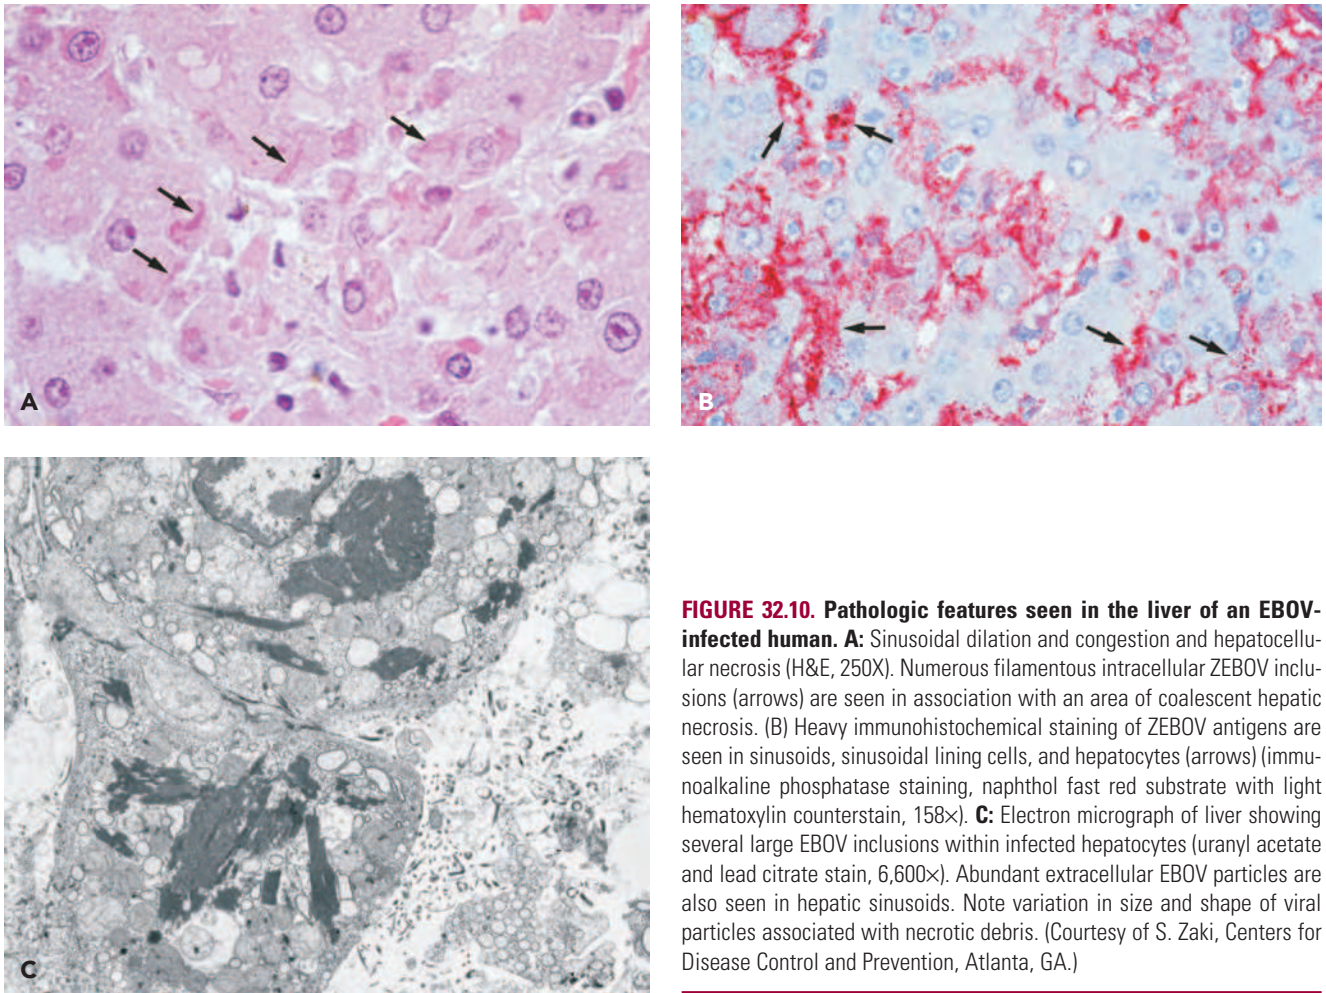

FIGURE 32.10. Pathologic features seen in the liver of an EBOV-infected human. **A:** Sinusoidal dilation and congestion and hepatocellular necrosis (H&E, 250X). Numerous filamentous intracellular ZEBOV inclusions (arrows) are seen in association with an area of coalescent hepatic necrosis. **(B)** Heavy immunohistochemical staining of ZEBOV antigens are seen in sinusoids, sinusoidal lining cells, and hepatocytes (arrows) (immunoalkaline phosphatase staining, naphthol fast red substrate with light hematoxylin counterstain, 158X). **C:** Electron micrograph of liver showing several large EBOV inclusions within infected hepatocytes (uranyl acetate and lead citrate stain, 6,600X). Abundant extracellular EBOV particles are also seen in hepatic sinusoids. Note variation in size and shape of viral particles associated with necrotic debris. (Courtesy of S. Zaki, Centers for Disease Control and Prevention, Atlanta, GA.)

tropism likely plays an equally important role in the disease pathogenesis. Elevations in liver enzymes are prominent findings in most filovirus infections.^{109,135,137,174,175,201,273,342} Various degrees of hepatocellular degeneration and necrosis have been reported in filovirus infections of humans and nonhuman primates.^{4,122,127,137,174,201,294,296,342,468,471} The hepatocellular lesions are generally not significant enough to explain the cause of death. However, impairment of the liver could contribute to the overall pathogenesis as hemorrhagic tendencies in some cases may be related to decreased synthesis of coagulation factors and other plasma proteins as a result of severe hepatocellular necrosis.

Adrenocortical infection and necrosis were also reported in filovirus infections of humans and nonhuman primates.^{127,137,138,174,342} The adrenal cortex plays an important role in blood pressure homeostasis. Impaired secretion of steroid-synthesizing enzymes leads to hypotension and sodium loss with hypovolemia, which are important elements that have been noted in nearly all cases of filovirus disease. This suggests that impairment of adrenocortical function by viral infection may contribute to the development of shock that typifies late stages of disease.

Host Immune Response

For both EBOV and MARV, lymphoid depletion and necrosis are commonly seen in spleen, thymus, and lymph nodes

of fatal cases and in experimentally infected nonhuman primates.^{4,118,122,123,137,138,174,296,342,468,471} Although lymphoid tissues are primary sites of filovirus infection, there is usually little inflammatory cellular response in these tissues or other infected tissues. Lymphopenia is a consistent finding among filovirus infections of humans and nonhuman primates.^{83,110,112,127,137,174,201,328,351,368} Despite the massive die off and loss of lymphocytes during filovirus infection, the lymphocytes themselves have not been shown to be infected. For both EBOV and MARV, large numbers of lymphocytes undergo apoptosis in humans and experimentally infected nonhuman primates^{4,9,11,134,137,174,327,438} in part, explaining the progressive lymphopenia and lymphoid depletion at death. In the 2000 outbreak of SEBOV in Uganda, numbers of T lymphocytes were lower in fatal cases than in nonfatal cases.³⁵¹ In the ZEBOV and MARV macaque models, the lymphocyte loss appears to be greatest among the T-lymphocyte and NK-cell populations.^{118,137,327}

The mechanism(s) for the underlying apoptosis and loss of “bystander” lymphocytes during the course of filovirus illness is unknown but is thought to be provoked through several different agonists or pathways. These pathways or processes may include the TNF-related apoptosis-inducing ligand (TRAIL) and Fas death receptor pathways,^{137,177,438} impairment of dendritic cell function,^{34,35,137,174,177,268} abnormal production of

soluble mediators such as nitric oxide (NO) that have proapoptotic properties,^{10,137,177,351} or possibly by direct interactions between lymphocytes and filovirus proteins. Severe cases of EHF have a prolonged high virus load, and one study of SEBOV-infected humans reported peripheral blood mononuclear cell unresponsiveness during the acute phase of disease.³⁵¹ The recognition of an immunosuppressive motif in the C-terminal region of the EBOV and MARV glycoproteins^{48,411,460} supports the premise that filovirus particles/proteins may contribute in part to the dysfunction and/or loss of lymphocytes.⁶³ A recent study has also suggested that the dramatic loss of lymphocytes that occurs during filovirus infection may be a result of the superantigen activity of filoviruses.²⁴⁷ In this study, human ZEBOV infection was associated with mRNA downregulation of three T-cell receptor (TCR) V β subsets, indicating either anergy or deletion of these T-lymphocyte populations.

Filovirus infection of humans and nonhuman primates triggers the expression of a number of inflammatory mediators including the interferons, interleukin (IL)-6, IL-8, IL-10, IL-12, interferon-inducible protein (IP)-10, monocyte chemoattractant protein-1 (MCP-1), regulated upon activation, normal T-cell expressed and secreted (RANTES), TNF- α , and reactive oxygen and nitrogen species.^{9,10,83,135,137,174,177,186,187,351,408,438} Infection of various primary human cells *in vitro* also shows that filovirus infection can trigger the production of many of these same inflammatory mediators.^{96,146,159,160,177,374} Overall, it appears that virus-induced expression of these mediators results in an immunologic imbalance that contributes to the progression of disease. However, information regarding the inflammatory response after filovirus infection has not been fully delineated and there are some differences in data among studies. For example, high levels of circulating interferon (IFN)- α were noted in acute-phase sera of patients infected with ZEBOV in one study⁴⁰⁸ but not detected in a subsequent similar study.¹⁰ Such differences complicate interpretation of some *in vitro* data as well. The differences in profiles of circulating cytokines and chemokines may be due to factors other than the differences among the filovirus species or strains assessed such as genetic differences among patient populations, and in particular, differences related to the disease phase when the samples were obtained.

For ZEBOV, there has been a report of patients with asymptomatic, nonfatal infections.^{244,246} It was proposed that these infections are controlled by an initial increase in cytokines including IL-1 β , IL-6, and TNF- α that is followed by a return to baseline levels. Results of this study suggest that protection from development of a fatal infection may depend on an early and robust cytokine response; however, this remains to be proven. On the other hand, disease severity may also be increased by an inappropriate proinflammatory response early in the course of infection; therefore, the balance between protective and detrimental proinflammatory responses remains to be defined.

Inhibition of the type I IFN response appears to be a feature of filovirus pathogenesis, and was initially indicated by studies of ZEBOV-infected endothelial cells.^{166,167} Subsequently, the EBOV protein VP35 was shown to function as a type I IFN antagonist^{19,20–21} by blocking interferon regulatory factor (IRF-3) activation and possibly preventing transcription of IFN- β .¹⁹ This activity of the ZEBOV VP35 has been linked to a C-terminal motif (³⁰⁵RACQKSLR³¹²)¹⁷² that is similar in sequence to the RNA-binding domain of the influenza A NS1 protein (interferon antagonist). In addition to VP35, other

studies suggest that EBOV VP24 expression interferes with type I IFN signaling^{20,329}; mutations in VP24 have also been linked to adaptation of ZEBOV to produce lethal disease in mice⁸⁴ and guinea pigs.⁴¹² Interestingly, MARV utilizes a different mechanism to evade the host IFN response. Recent studies have shown that MARV VP40 blocks the phosphorylation of Janus kinases and their target STAT proteins in response to type I and type II interferon and IL-6.⁴⁰⁶ Mutations in VP40 have been linked to adaptation of MARV to produce lethal disease in mice²⁶³ and guinea pigs.²⁶²

Several studies indicate an important role for reactive oxygen and nitrogen species in filovirus disease pathogenesis. Increased blood levels of NO were reported in nonhuman primates experimentally infected with ZEBOV^{137,177} and were also noted in ZEBOV- and SEBOV-infected patients.^{10,351} Significantly, increased blood levels of NO in patients was associated with mortality.³⁵¹ Abnormal NO production has been associated with a number of pathologic conditions including apoptosis of bystander lymphocytes (as noted previously), tissue damage, and loss of vascular integrity, which may contribute to virus-induced shock. NO is known to have both protective and caustic effects; this autotoxic overproduction may represent the host's endogenous counter-regulatory mechanism of protection against noxious agents, in this case the filoviruses. In general, microbes induce monocytes and macrophages to produce NO in an attempt to control infection. However, in the case of the filoviruses, monocytes and macrophages are preferred host cells for viral replication. Enhanced replication in these cells may in turn exacerbate disease by producing large amounts of NO, resulting in deleterious effects such as suppressive effects on lymphocyte proliferation and damage to other cells. NO is an important mediator of hypotension, a prominent finding in most VHF including those caused by filoviruses.¹⁴⁰

Together, the information collected to date suggests that an impaired and ineffective immune response leads to high levels of virus and proinflammatory mediators in the late stages of disease, which are important for the pathogenesis of hemorrhage and shock. Indeed, the prevailing hypothesis at this time is that infection and activation of monocytes/macrophages is fundamental to the development of EHF and MHF, and that it is the release of proinflammatory cytokines, chemokines, and other mediators that causes impairment of the vascular and coagulation systems (discussed in the following section) leading to multiple organ failure and a syndrome that in some ways resembles septic shock.^{39,41,135,137,140,145,160,174,177,267,358,359,360,374,420}

Impairment of the Vascular System

The endothelium is thought to play an important role in the pathogenesis of EBOV and MARV, although studies defining the molecular mechanisms of endothelial impairment are incomplete. It was speculated that EBOV GP is the primary determinant of vascular cell injury and that EBOV infection of endothelial cells induces structural damage,⁴⁶³ which could contribute to hemorrhagic diathesis. Human and nonhuman primate endothelial cells are susceptible to EBOV and MARV infection,^{135,166,167,360,361} but while *in vitro* studies have reported some cytopathic effects associated with filovirus replication, in general, filovirus replication in nonhuman primates did not induce overt cytopathology. In fact, in one study using primary human endothelial cells, ZEBOV infection induced an upregulation of protective antiapoptotic genes.¹⁴⁶

EBOV and MARV infection of endothelial cells *in vivo* has been documented, as noted previously, but human data is sparse. ZEBOV antigens were readily detected in endothelial cells of a variety of tissues during the 1995 Kikwit outbreak.⁴⁶⁸ On the other hand, an immunohistochemical survey of a fatal case of MARV infection showed infrequent infection of endothelial cells in the tissues examined.¹³⁸ Clearly, disturbance of the blood tissue barrier is an important component of filovirus disease, and direct infection and destruction of endothelial cells cannot completely be dismissed as contributing to the hemorrhagic diathesis. However, histologic observations of autopsy tissues from several of the early filovirus outbreaks failed to identify the presence of vascular lesions²⁹⁴ and there have been no reports of vascular lesions in any subsequent studies to date. There is also no evidence of significant vascular lesions in filovirus-infected nonhuman primates.^{17,18,73,135,174,201,342}

In temporal studies in nonhuman primates, ZEBOV and MARV infection of endothelial cells was infrequent and primarily restricted to the terminal stages of disease.^{135,174} In these animals, the endothelium remained relatively intact morphologically, although increased vascular permeability was observed. This is consistent with the imbalance of fluid between the intravascular and extravascular tissue spaces observed in patients. Using *in vitro* systems, increased endothelial permeability was associated temporally with the release of TNF- α from MARV-infected human monocytes/macrophages.⁹⁶ Subsequent studies showed that EBOV-induced cytokine release led to activation of the endothelium, as demonstrated by a breakdown of barrier function,⁴²¹ providing further evidence that endothelium may be affected indirectly by a mediator-induced inflammatory response of primary target cells more so than by direct filovirus replication-induced cytopathology. It is important to keep in mind, when comparing results among studies, that differences in findings could represent differences between macaque models and human disease possibly through the divergence of endothelial cell receptors such as DC-SIGNR. Nonetheless, and as noted previously, most studies indicate that changes in integrity of the endothelium are influenced primarily by local or systemic increases in levels of cytokines and other host-cell factors triggered by infection.

Impairment of the Coagulation System

Defects in blood coagulation and fibrinolysis during EBOV and MARV infections are manifested as petechiae (Fig. 32.11), ecchymoses, mucosal hemorrhages, congestion, and uncontrolled bleeding at venipuncture sites. However, massive loss of blood is infrequent and, when present, is primarily limited to the gastrointestinal tract. In fact, even in these cases, the amount of blood that is lost is not significant enough to account for death. Thrombocytopenia, consumption of clotting factors, and increased levels of fibrin degradation products are other indicators of the coagulopathy that characterizes EBOV and MARV infections.

Although disseminated intravascular coagulation (DIC) is often viewed as a prominent manifestation of filovirus infection in primates, evidence of DIC in human filovirus infections is sparse primarily due to difficulties encountered in performing studies in inaccessible geographic settings. Clinical laboratory data suggest that DIC is an important feature of human EHF.^{197,334,449} D-dimer levels were substantially increased in all patients with SEBOV infections but were four times higher in

patients with fatal disease than in patients who survived.³³⁴ The coagulation picture is clearer for nonhuman primates. Numerous studies have shown histologic and biochemical evidence of DIC syndrome during EBOV infection in a variety of nonhuman primate species.^{17,40,73,83,109,111,112,141,145,146,176,201,342} For MARV, histologic or biochemical evidence of DIC has been reported in a handful of available cases^{122,138} and in a few studies of experimentally infected monkeys.^{127,174,471}

Despite any differences between humans and nonhuman primates regarding DIC, impairment of coagulation ostensibly contributes to the disease pathogenesis of EHF and MHF (Figs. 32.9 and 32.11). The mechanism(s) responsible for triggering the coagulation disorders is not completely understood. Several studies suggest that development of coagulation abnormalities might occur much earlier than previously thought. For example, in one study, markedly elevated levels of D-dimers were detected one day after experimental infection of cynomolgus monkeys with ZEBOV, which occurred two days before the detection of viremia in these animals.¹⁴⁵ Although it is likely that the coagulopathy seen during filovirus infections is caused by a number of factors, particularly during the later stages of disease, data strongly implicate tissue factor expression/release from EBOV-infected monocytes/macrophages as a key factor that induces the development of coagulation irregularities.¹⁴⁵ Of course, as noted previously, other factors may also contribute to the coagulopathy associated with filovirus infections. For example, impairment of the fibrinolytic system was documented by rapid declines in plasma levels of protein C during the course of ZEBOV infection of cynomolgus and rhesus monkeys.^{83,145,176}

Virulence

The virulence of filoviruses in humans is highly variable depending primarily on the species or strain; a similar variability seems to recapitulate well in nonhuman primates. Among the EBOV species, ZEBOV is the most virulent and REBOV appears to be the least virulent. Infection of nonhuman primates with ZEBOV usually progresses rapidly and is uniformly lethal, with as little as one infectious unit being required to cause disease. The course of disease appears to be influenced by the dose of filovirus used. As an example, cynomolgus macaques exposed by intramuscular injection with a low challenge dose of ZEBOV (10 pfu) succumbed to infection 8 to 12 days after challenge,³⁷⁷ but when exposed to a high dose (1,000 pfu) died 5 to 8 days after challenge.^{137,143} Likewise, a similar protraction of disease course in nonhuman primates concurrent with serial dilution was noted for MARV.¹⁵³

In human cases, route of infection ostensibly affects the disease course and the outcome. The mean incubation period for cases of ZEBOV known to be due to injection was 6.3 days, versus 9.5 days for contact exposures.⁴³ Moreover, the CFR in this 1976 ZEBOV outbreak was 100% (85 of 85) in cases associated with injection compared with ~80% (119 of 149) in cases of known contact exposure.⁴³ Although the nonhuman primate models appear to be exquisitely sensitive to the filoviruses compared to humans, particularly for ZEBOV, this observation in part could relate to the fact that most nonhuman primate studies involve intramuscular injection with very high challenge doses.

Fewer studies have evaluated the pathogenesis of SEBOV in nonhuman primates.^{86,109} The disease course in experimentally infected rhesus and cynomolgus macaques appears much

FIGURE 32.11. Hemorrhagic manifestations seen in nonhuman primates acutely infected with filoviruses.

Shown are examples of petechiae evident on (A) the upper torso and arms of a rhesus macaque infected with ZEBV (strain Mayinga 1976) (A), the head and neck of a rhesus macaque infected with MARV (strain Angola 2005) (B), and the lower trunk and leg of a cynomolgus macaque infected with SEBOV (strain Gulu 2000) (C). Also shown are a gastroduodenal lesion (D) and hemorrhage in the ileum (E) of a SEBOV-infected cynomolgus macaque (Courtesy of A. Sanchez and P. Rollin (A), Centers for Disease Control, Atlanta; T.W. Geisbert (B, C) US Army Medical Research Institute for Infectious Diseases (USAMRIID), Frederick; and T. Larsen (D,E), USAMRIID, Frederick).

slower than that seen in ZEBV infections, and the rates of survival appear consistent with human disease. SEBOV infection was not lethal in a small cohort of African green monkeys nor was REBOV.¹⁰⁹ Similar to SEBOV, the disease course in REBOV-infected cynomolgus monkeys is protracted.²⁰⁵ Experimental infection of cynomolgus macaques by intramuscular injection with 1,000 pfu of SEBOV results in 50% to 100% mortality, with deaths typically occurring 7 to 12 days after infection. In comparison, experimental infection of cynomolgus macaques with 1,000 pfu of REBOV results in 80% to 100% mortality, with deaths usually occurring 8 to 21 days after infection. Recent studies have shown similar results for CIEBOV and BEBOV. Specifically, experimental infection of cynomolgus macaques with 1,000 pfu of CIEBOV resulted in 60% mortality, with deaths occurring 12 to 14 days after

infection¹³¹ while infection with 1,000 pfu of BEBOV resulted in 75% mortality, with deaths occurring 11 to 14 days after infection.^{92,175}

There appears to be some difference in virulence among the strains of MARV. Historically, virulence of the MARV strains in humans has been comparable to SEBOV. However, virulence of the recently isolated Angola strain appears to be more consistent with ZEBV. Most strains of MARV produce near uniformly lethal infections in cynomolgus and rhesus macaques. Among the MARV strains, infections of macaques with the Angola strain appear to progress more rapidly than other strains. For example, challenge of rhesus macaques by intramuscular injection with 1,000 pfu of the Musoke strain produces a uniformly lethal infection, with deaths occurring 10 to 12 days after infection, whereas an identical challenge of

rhesus macaques with 1,000 pfu of the Angola strain resulted in deaths occurring 6 to 8 days after challenge.¹²⁷

Currently, the variability in virulence in primates within and between species of filoviruses is unclear, but for EBOV there has been some speculation that the GP has a major influence on virulence.⁴⁶³ Studies have shown that unlike ZEBOV, expression of the GP from REBOV did not disrupt the vasculature of human blood vessels. It was initially reported that the expression of the EBOV GP caused significant cell death in cultured cells^{462,463}; however, subsequent studies showed that most of the detached cells (>90%) were still viable,^{57,367} suggesting that GP expression may interfere with cell attachment without triggering cell death. It has been speculated that EBOV may control GP cytotoxicity by regulating its expression through RNA editing,⁴¹⁵ but this mechanism needs to be studied in cells derived from the natural host and reconciled with the importance/role of sGP expression.

EBOV produces five soluble glycoproteins during infection: sGP, Δ -peptide, GP₁, GP_{1,2Δ}, and the newly identified ssGP.²⁸¹ MARV produces GP₁ and presumably GP_{1,2Δ}.¹⁰⁵ Upon the discovery of sGP, it was logical to attempt to correlate the higher pathogenicity of EBOV with its expression; however, the EBOV-like virulence and mortality rates associated with the Angola strain of MARV⁵⁵ dispel any such associations. Additionally, the lower virulence of REBOV and CIEBOV does not support a role in virulence for sGP.¹⁰⁵ The contribution of the secreted GPs to the disease pathogenesis of EBOV and MARV remains largely unknown, but recent studies have begun to examine the effects of EBOV GPs on the host response to infection. Initial studies suggested that the EBOV sGP interfered with innate immunity by binding to CD16b and inhibiting neutrophil activation.^{227,462} However, subsequent studies questioned these findings and in contrast showed that neutrophils do not express a receptor for EBOV sGP.³⁷⁶ Other studies have evaluated the role of the secreted GPs in activating macrophages and endothelial cells. For example, studies using primary human macrophages and endothelial cells concluded that the presentation of the EBOV GP_{1,2} in a membrane-bound form (on virions or VLPs) is sufficient for activation of these cells.^{420,421} However, these studies also showed that none of the four secreted EBOV GPs was capable of activating human macrophages, and neither sGP nor delta peptide were capable of activating endothelial cells. In fact, sGP protected endothelial cell barrier function⁴²⁰ and could counteract or lessen the cytotoxicity caused by EBOV GP. Furthermore, it has been proposed that soluble glycoproteins circulating in the blood of virus-infected animals may play an important role in pathogenesis by efficiently blocking the activity of virus-neutralizing antibodies.^{78,105,200}

Host Genetics

Recent studies have shown that the outcome of filovirus infection could in part be determined by host genetics. Sequence-based HLA-B typing was performed on patients from the 2000 outbreak of SEBOV in Uganda.³⁵⁵ In this study, statistically significant associations were found between certain sets of alleles and either fatal or nonfatal disease outcomes. Alleles B*67 and B*15 were associated with fatal outcomes, whereas B*07 and B*14 were associated with nonfatal outcomes. In a different study, the association of KIR genotype with disease outcome was determined by comparing genotypes of a Gabonese

control population, IgG+ contacts, survivors, and fatalities of ZEBOV infection.⁴³⁹ In this study, the activating KIR2DS1 and KIR2DS3 genes were associated with fatal outcome.

Persistence

As noted earlier, mortality rates for EBOV and MARV are high and few patients survive infection. In survivors, levels of circulating virus in the blood decline as the patient recovers.^{235,351} However, during the recovery phase several lines of evidence suggest that EBOV and MARV may persist in humans in immunologically privileged sites. In one laboratory-acquired infection, EBOV was isolated from semen samples 39 and 61 days after the onset of illness.⁸⁷ After the 1995 outbreak of ZEBOV in Kikwit, infectious virus was recovered from seminal fluid of one patient 82 days after disease onset, while viral RNA was detected in semen samples of three additional patients between 63 and 101 days after the onset of illness.^{333,338} For MARV, sexual transmission was reported in one case during the original outbreak in Marburg, Germany in 1967, with semen apparently containing infectious virus more than 12 weeks after clinical recovery.²⁷⁵

EPIDEMIOLOGY

Because much of the early serosurvey data has been based on the fluorescent antibody test, a subjective and unreliable assay, identification of the geographic range of filoviruses is more accurately determined from filovirus outbreaks. ZEBOV, SEBOV, and CIEBV and BEBOV are found in the African tropical forest or nearby savanna and occasionally emerge often during the rainy season.¹⁵⁵ REBOV has been linked only to a single export nonhuman primate facility in the Philippines and more recently to a few pig farms in the country.^{14,285} Based on current data and the new discovery of REBOV on pig farms in the Philippines,¹⁴ REBOV is most likely an Asian filovirus, possibly derived from certain fruit bat species in the forests of the Philippines.⁶⁹ Alternatively, the REBOV strains could represent derivatives from a single introduction (most likely Africa) through bat migration or importation, and subsequent establishment and circulation in the Philippines. MARV has apparently been contracted in forested and derived areas of Kenya, Uganda, Zimbabwe, the DRC, and recently Angola, but in several cases the epidemiologic information does not provide an adequate description of the environment where infections were suspected to have occurred. The European outbreak from 1967 was initiated through imported infected African green monkeys and could be traced to a source in Uganda. The animals were compounded in Entebbe (central holding station at Lake Victoria) and shipped via London (where they had potential contact with other animals) to Germany and the former Yugoslavia.

The epidemiology of human infections in nature, besides the internationally recognized outbreaks, is unknown. However, the time elapsed between occurrence of the index cases and the recognition of the subsequent large outbreaks suggests that sporadic cases of unrecognized filovirus infections could readily pass unnoticed.²¹² The number of such identified clusters in the past decade may represent a combination of unidentified ecologic factors and increasing diagnostic interest. Serologic surveys revealed EBOV antibody prevalence from 10.2% among gold panners in Gabon to 9.3% among rural villagers in the

DRC using enzyme-linked immunoabsorbent assay (ELISA)-based technology. EBOV infection, potentially with nonpathogenic strains/variants or strains/variants of low pathogenicity, may be frequent in select rural African populations.^{147,216}

Whatever the source of the initial index case, person-to-person transmission is the means by which human filovirus outbreaks have been propagated. This generally involves intimate contact; secondary attack rates have not exceeded 10% to 15%, indicating that transmission is not efficient. However, this risk increases as a function of contact. For example, during the 1976 SEBOV outbreak 23% of family members sleeping in the same room as the patient were infected, compared to 81% of persons providing active nursing care to a patient.¹³ The need for this intimacy is reflected in the relative paucity of infected children, who are less likely to be primary care givers for ill family members.⁷⁹ Nosocomial transmission is a special problem and hospitals have often served as a source of disease amplification into the community and to health care workers. A quarter of all cases during the 1995 ZEBOV outbreak were among health care workers. Extreme care should be taken with infected blood, secretions, excretions, tissues, and hospital materials and waste. Well-documented and surreptitious reuse of needles and syringes has also played a role in these outbreaks. No person whose contact was exclusively parenteral during the 1976 ZEBOV outbreak survived. Sexual transmission has been reported with MARV and can also be assumed for EBOV (discussed earlier).

There is a striking difference in the ZEBOV epidemics in Gabon/RC compared to those caused by most other filoviruses including ZEBOV outbreaks at other sites. Most of the epidemics in this area are limited in case numbers and are related to contact with wildlife (chimpanzees, gorillas, and other species). Epidemiologic and genetic investigations showed that outbreaks resulted from the introduction of distinct strains, indicating that multiple ZEBOV strains were co-circulating in this region. All index cases (mainly hunters) were infected by handling dead or wounded animals, and subsequently led to person-to-person transmission within their families. In many instances human infections have been preceded by disease in wildlife, and these infected animals acted as either dead-end hosts or interim/amplification hosts.^{106,250} Multiple introductions of MARV lineages were also noticed in the MARV outbreak in Durba/Watsa.^{22,23,65,400,401}

Filoviruses are transmissible to nonhuman primates in the laboratory by aerosols,^{25,217} and virions have been identified in alveoli of infected monkeys and humans.^{141,202,469,470} Furthermore, the outbreak caused by REBOV among quarantined monkeys in 1989/1990 was strongly suggestive of droplet and/or small-particle aerosol transmission. However, these animals were housed in a poorly ventilated building in which aerosols could have been generated by cleaning procedures.²⁰⁵ Aerosol transmission has not been unequivocally implicated in human outbreaks to date. Interestingly, extremely efficient person-to-person transmission has been attributed to two individuals who may have been the source of infection for over 50 cases in the 1995 ZEBOV outbreak.²²³ The mechanism of this heightened transmission was not identified, although contact with the patient and/or cadaver was strongly implicated. Despite little evidence for aerosol transmission in nature, this is the most likely route used for delivery of filoviruses in a deliberate act.

ECOLOGY

The natural reservoir(s) of filoviruses remains elusive despite increased numbers of outbreaks and opportunities to investigate their origins.^{106,155,318} As classical zoonotic agents, these viruses likely persist in an animal (or several animals) or arthropods, which transmit the virus directly to humans, great apes, nonhuman primates, or an interim amplifying host.^{113,288}

Lack of replication in arthropod cells or inoculated arthropods⁴⁰⁴ argues against such an intermediary for filoviruses, and extensive arthropod field surveys have failed to detect the presence of EBOV. It has been suggested that human contact with filovirus-infected bats may have initiated the early SEBOV outbreaks in Sudan,⁸ the ZEBOV outbreak in the DRC in 2007²⁴⁸ and the MARV infections in Kenya.^{218,371} In addition, the outbreak of MHF in the northeast region of the DRC had some connection, directly or indirectly, with a bat-infested gold mine.²² Interestingly, experimental infection of wild African fruit and insectivorous bats has shown that these animals are capable of supporting the replication of EBOV without becoming ill, despite high levels of circulating virus.³⁸³ Recent findings of asymptomatic EBOV and MARV infections in fruit bats are additional evidence that such animals are capable of harboring filoviruses and may serve as reservoir species; in particular *Rousettus aegyptiacus* for MARV.^{249,400} Because persistently infected hosts are postulated for zoonotic diseases, chronic infection in bats or other small animal species is likely involved in the ecology of filoviruses.^{317,318}

The epizootics caused by REBOV have raised the question as to whether nonhuman primates act as reservoirs for filoviruses.²⁸⁵ This seems unlikely for the African filoviruses, which are highly pathogenic for nonhuman primates, and this trait is generally incongruous with the concept of a reservoir host. In addition, there has been no evidence for latent virus infection in these animals.^{109,113} If monkeys are not the reservoir, they at least act to amplify the virus in the wild, and unexplained disease/mortality in these animals could be an indicator of impending transmission in humans. This is supported by reported deaths in monkey species prior to outbreaks of CIEBOV in the Tai Forest,²⁴³ several of the ZEBOV outbreaks occurring since 1996 in Gabon,^{250,252} and a more recent outbreak of ZEBOV in the RC.¹¹⁵ Investigations into the outbreaks in Gabon/RC confirmed this concept and showed multiple introductions of different ZEBOV strains from an unknown reservoir into wildlife that then served as sources of initial human infections.^{250,337} In contrast, filovirus sequences from patients involved in a distinct epidemic chain of human cases were conserved, indicating that these episodes were mainly caused by single-source introductions.^{245,250,333} Thus, it appears that distinct filovirus strains have evolved to occupy undefined ecologic niches throughout the forests of Central Africa, and that the potential for human contact with these agents is greatly increased when viruses are circulating in indigenous nonhuman primate populations.

Beginning in 1994, the frequency of filovirus outbreaks in Africa increased and shows no sign of diminishing. Future episodes of EBOV and MARV transmission are unavoidable, which poses a serious risk to human populations, but also threatens to decimate the world's largest populations of gorillas

and chimpanzees.^{100,250,422} This dangerous situation makes the identification of the natural reservoir an important objective for the scientific community, which needs to improve and formulate new working hypotheses and strategies. Efforts at ecologic niche modeling from data gleaned from outbreaks and sporadic cases have revealed a different Afrotropic distribution for filoviruses, with EBOV more likely to occur in the humid rain forests of Central and Western Africa and MARV in the drier and more open areas of Central and East Africa.^{155,317} Future surveillance at existing field sites (e.g., Tai Forest, Ivory Coast; Watsa/Durba, DRC; Gabon, DC; Uíge, Angola) should focus on affected animal populations, such as great apes, and possibly include the use of sentinel animals. Experimental studies of potential reservoir species should be initiated and/or intensified to better understand filovirus persistence and transmission.

CLINICAL FEATURES

Filovirus infections are generally the most severe of the VHF, but only limited information is derived from close observations of acute human cases. Differences in the clinical syndromes caused by filoviruses may exist, but there have been few opportunities for close observation of the diseases under favorable conditions.^{13,51,97,102,114,122,197,210,211,276,282,312} The abrupt onset follows an incubation period of 2 to 21 days, averaging 4 to 10 days, and is characterized by flu-like symptoms (fever, chills, malaise, and myalgia; Fig. 32.12). The subsequent signs and symptoms indicate multisystem involvement and include systemic (prostration), gastrointestinal (anorexia, nausea, vomiting, abdominal pain, diarrhea), respiratory (chest pain, shortness of breath, cough), vascular (conjunctival injection, postural hypotension, edema), and neurologic (headache, confusion, coma) manifestations. Hemorrhagic manifestations develop during the peak of the illness and include petechiae, ecchymoses, uncontrolled oozing from venipuncture sites, mucosal hemorrhages, and postmortem evidence of visceral hemorrhagic effusions. Often a macropapular rash associated with varying degrees of erythema

appears by days 5 to 7 of the illness; this is a valuable differential diagnostic feature and is usually followed by desquamation in survivors. Abdominal pain is sometimes associated with hyperamylasemia and true pancreatitis. In later stages, shock, convulsions, severe metabolic disturbances, and, in more than half the cases, diffuse coagulopathy supervenes (Fig. 32.12).

Laboratory parameters are less characteristic but the following findings are associated with the disease. There is an early leukopenia (as low as 1,000/ μ L) with lymphopenia and subsequent neutrophilia, left shift with atypical lymphocytes, thrombocytopenia (50,000–100,000/ μ L), markedly elevated serum transaminase levels (AST typically exceeding ALT), hyperproteinemia, and proteinuria. Prothrombin and partial thromboplastin times are prolonged and fibrin split products are detectable. In a later stage, secondary bacterial infection may lead to elevated white blood counts.

Nonfatal cases have fever for about 5 to 9 days and improvement typically occurs around days 7 to 11, about the time the humoral antibody response is noted.²³⁵ Convalescence is prolonged and sometimes associated with myelitis, recurrent hepatitis, psychosis or uveitis.^{97,102,276,282,338} There is an increased risk of abortion for pregnant women, and clinical observations indicate a high death rate for children of infected mothers. Fatal cases develop clinical signs early during infection and demise typically occurs between days 6 and 16, due to hemorrhage and hypovolemic shock. The mortality from ZEBOV infections is high (60–90%), SEBOV and BEBOV somewhat lower (50–60% and 25–35%, respectively), and MARV probably around 70% to 85%, with the exception of the outbreak in Europe (only 23%).^{97,282} The single observed Ivory Coast infection case survived, as did a second serologically diagnosed case. The few REBOV infections/exposures identified so far in Reston, Virginia and in the Philippines had no symptoms, but one patient (accidentally infected during a necropsy of an infected monkey) yielded a serum virus isolate. Thus, it is generally assumed that REBOV has a reduced pathogenicity or is apathogenic for humans, but this judgement may be premature and needs further investigation.

FIGURE 32.12. Graph showing time frames, relative to the time of disease onset, for the sensitivity of diagnostic assays and the development of signs and symptoms associated with severe filovirus infections. Dashed areas on arrows indicate approximate times where clinical features of disease or assay targets can be negative/absent or difficult to detect.

DIAGNOSIS

Clinical Diagnosis

Filovirus disease can be suspected in acute febrile patients with symptoms, as described earlier, and a history of travel to an endemic area. Identification may be difficult, due to a wide variety of infectious diseases causing similar clinical symptomatology. The most common causes of severe, acute, febrile diseases in filovirus-endemic areas are malaria and typhoid fever. A wide range of infectious diseases must also be considered, such as shigellosis, meningococcal septicemia, plague, leptospirosis, anthrax, relapsing fever, typhus, murine typhus, yellow fever, Chikungunya fever, and fulminant viral hepatitis. Rural travel, jungle or cave exposure, treatment in local hospitals, contact with sick persons or wild and domestic animals, particularly monkeys and apes, are useful historical features, especially in travelers returning from Africa. For patients with filovirus disease, prostration, lethargy, wasting, and diarrhea seem to be more severe than is seen with other VHF infections; the appearance of a characteristic rash is useful in narrowing the differential diagnosis. Diagnosis of single cases is extremely difficult, but the occurrence of clusters of cases with prodromal fever followed by hemorrhagic diatheses and person-to-person transmission is suggestive of VHF and require the implementation of containment procedures.

Laboratory Diagnosis

Despite the capabilities of laboratory diagnostics, it should be kept in mind that initial diagnosis of filovirus infections will be based on clinical assessment. Clinical microbiology and public health laboratories are generally ill equipped to diagnose VHF infections, particularly those caused by filoviruses, so specimens should be sent to national and/or international reference laboratories capable of performing the required testing. In addition, many nations encounter difficulties in sample transport, which can cause substantial delays in laboratory response. Once samples are received by appropriate reference laboratories, response is fairly efficient.

During outbreaks health care workers, who have direct contact with patients, are at high risk for infection; adequate barrier nursing precautions should be implemented in the collection of samples.^{314,373} Special care should be taken to avoid needle sticks and to immediately dispose of contaminated material in an appropriate manner. Collection of specimens should be done facilitating sterility and prevention of cross-contamination of specimens. This has become particularly important for ultra-sensitive techniques such as reverse transcriptase–polymerase chain reaction (RT-PCR).³⁷³ Filoviruses are relatively stable and infectious particles can survive less than favorable handling and shipping for months. Care should be taken to ensure the physical integrity for biosafety reasons and to maintain an adequate refrigerated or frozen state for biologic integrity of the sample to maximize the reliability of diagnostic results.

Laboratory diagnosis of filovirus infections can be achieved in two ways: measurement of host-specific immune responses to infection and detection of virus particles or particle components (RNA and protein) in infected individuals (Table 32.3). Today, RT-PCR^{81,151,350,373,402} and antigen detection ELISA^{193,234,235,265,266,304,373} are the primary test systems to diagnose an acute infection. For antibody detection the most commonly used assays are direct IgG and IgM ELISAs and IgM capture ELISA.^{195,235,236,373} RT-PCR, antigen detection, and serology can be performed on materials that have been rendered non-infectious by radiation or chemicals. Gamma irradiation is an efficient means of inactivating specimens prior to antigen detection and serology and is achieved by exposure to a cobalt-60 source. Samples for RT-PCR (nucleic acid extraction) can be treated with guanidinium isothiocyanate, a chaotropic agent that denatures proteins and renders the sample noninfectious. These methods of inactivation allow the safe manipulation of material outside of the containment laboratory, where work can be carried out more expeditiously.

Other serologic tests that have been used in filovirus diagnosis are the western blot assay (can be used as a confirmatory assay) and the indirect immunofluorescence assay (IFA; occasionally used as a screening assay) on gamma-inactivated, fixed

TABLE 32.3 Laboratory Assays Used in the Diagnosis of Filovirus Infections

Test	Target	Source	Remarks
A. Primary Assays			
Polymerase chain reaction (PCR)	Viral nucleic acid	Blood, serum, tissues	Rapid and sensitive; requires special equipment
Antigen enzyme-linked immunosorbent assay (ELISA)	Viral antigen	Blood, serum, tissues	Rapid and sensitive; requires special equipment, but capable of high throughput
ELISA (IgM capture, IgG)	Antiviral antibodies	Serum	Rapid, specific, and sensitive; slower than IFA when testing small numbers of specimens
B. Confirmatory Assays			
Indirect immunofluorescence assay (IFA)	Antiviral antibodies	Serum	Rapid and simple to perform, but prone to nonspecific positives and subjective interpretation
Western blot	Antiviral antibodies	Serum	Protein specific; interpretation sometimes difficult
Immunohistochemistry	Viral antigen	Tissues (e.g., skin, liver)	Slow; material inactivated
Fluorescence assay (FA)	Viral antigen	Tissues (e.g., liver)	Rapid and easy, but interpretation is subjective
Electron microscopy	Viral particle	Blood, tissues	Unique morphology (immunostaining possible); insensitive and requires expensive equipment
Virus isolation	Viral particle	Blood, tissues	Slow; virus isolate available for studies

cells infected with EBOV or MARV or containing expressed recombinant filovirus proteins.^{194,215,216,373} Due to relatively high viremia levels in humans, electron microscopy has been helpful in diagnosis of filovirus infections but is not generally used.^{139,144,203,294,364} Filovirus particles present in sera and cell culture fluids (primary isolation) can be directly visualized by negative staining, and can be easily detected in thin sections of infected tissues, especially the liver and spleen. IHC on formalin-fixed material and paraffin-embedded tissues can be used for detection of filoviruses^{203,470} as well as immunofluorescence (IF) on impression smears of tissues.³³⁵ IHC is a very useful surveillance assay especially when no other specimens are available during an outbreak. Advantages of IHC testing include its simplicity and specificity but also lack of a need for enhanced biocontainment,^{260,469,470} as formalin-fixed biopsy specimens are not infectious, are easily generated, and can be transported without special precautions or refrigeration.

Isolation of infectious virus from serum or other clinical material is a relatively simple and sensitive procedure and should always be attempted if BSL-4 containment is available. Filoviruses grow well in a large variety of cell lines, although Vero cells (or the Vero E6 clone) have been most used, but often upon primary isolation the development of CPE may be subtle or lacking. Guinea pigs can be used for primary isolation of those filoviruses that initially do not grow well in tissue culture, but repeated passaging is usually required to produce severe/fatal disease. In addition, broad clinical syndrome-based technologies have been developed on the basis of multiplex PCR and pan-microbial oligonucleotide array technologies.^{259,309} These assays, however, have yet to be implemented into common diagnostic settings.

Of the available techniques for diagnosis, antigen-capture ELISA and RT-PCR are today the most useful for making a diagnosis in an acute clinical setting. Viral antigen/nucleic acid can be detected in blood as early as day -1 until past day 16 post-onset of symptoms (Fig. 32.12).^{97,282,338} RT-PCR assays seem to be favored by many investigators because BSL-4 biocontainment is not necessary after proper inactivation, as well as the sensitivity/specificity and rapidity of the technique.^{151,373} However, the diagnosis of index cases of outbreaks or of single imported cases should not be solely based on RT-PCR. Confirmation by an independent assay such as antigen-capture ELISA should always be attempted. When case confirmatory techniques and biocontainment (virus isolation) are not available, RT-PCR on an independent target gene and/or independent sample should be the minimum confirmation.¹⁵¹ In such instances it may be useful to seek confirmation through another reference laboratory, which is always preferred.

Serology can be useful for confirmation, but it should be kept in mind that a negative serology is inconclusive because filovirus-infected individuals often die without seroconversion. Based on past investigations, IgM antibodies can appear as early as 2 days post-onset of symptoms and disappear between 30 and 168 days after infection. IgG-specific antibodies develop between days 6 and 18 after onset and persist for many years (Fig. 32.12).^{97,282,338} A rising IgM or IgG titer constitutes a strong presumptive diagnosis. However, a single positive result should be confirmed on a follow-up sample, preferably at least a week apart. Decreasing IgM and/or increasing IgG titers (fourfold) in successive paired sera are highly suggestive of a recent infection.

Standardization and evaluation of diagnostic procedures for filoviruses is difficult because of the restricted availability

of virologic and clinical material. The European Network for Imported Viral Diseases (ENIVD) provides external quality assurance for filovirus RT-PCR diagnostic procedures.³⁰³ Continued and extended quality assurance studies are required to maximize the robustness of filovirus diagnostic procedures.

Filovirus outbreaks usually occur in remote areas where sophisticated medical support systems are limited and timely diagnostic services are extremely difficult to provide. Provision of a fieldable laboratory offering basic diagnostics for filoviruses and other agents that may be confounding to the diagnosis could aid in the management of patients specifically and the outbreak in general. The development of truly portable real-time thermocyclers and fieldable immunologic assays has made the deployment of a field diagnostic laboratory a reasonable undertaking. In setting up field diagnostics, the initial and most important consideration is to minimize the exposure of workers to infectious materials. This can be accomplished by setting up a portable class III biosafety cabinet, but the use of personal protective equipment, such as powered air-purifying respirators (PAPRs) is perhaps a more convenient and realistic means of protecting workers processing infectious material in the field. Clinical and other specimens can be safely heat inactivated (together with an appropriate ionic or nonionic detergent) for serologic analysis and with guanidinium isothiocyanate buffers for RNA isolation.^{151,402}

PREVENTION AND CONTROL

Patient Management

Devising a strategy for the prevention of primary filovirus infections of humans is problematic, as the natural reservoirs and factors that affect filovirus movement in the wild are still largely unknown. Assuming that bats serve as a reservoir, proper education seems the most feasible way of prevention.²⁴⁸ Except for instances in which infected great apes have been the source of infections, it is difficult to identify a human index case, let alone the type of contact that initiated the infection. However, once it enters a human or nonhuman primate population, it is clear that the virus is spread through close contact with acutely infected members. Isolation of patients and use of strict barrier nursing procedures, including the use of protective clothing and respirators, have been sufficient to rapidly interrupt transmission in the hospital.^{65,211} Cadavers from fatal cases represent a residual risk for community members, and unprotected handling of corpses should be avoided.³³² Under specific circumstances, the use of full-face respirators or PAPRs for protection against aerosols may be indicated (79; <http://www.cdc.gov/ncidod/dvrd/spb/mnpages/vhfmanual.htm>); an N95/N100 mask with face shielding can provide a good level of protection. Methods for implementing barrier nursing, waste disposal, and other key elements (inexpensive and practical in Africa) have been devised, and a field-tested manual is available.²⁶⁰ One of the important elements is provision of sterile equipment for injections, which are remarkably and tragically lacking in Africa today.

Therapeutic Options

Filovirus infections are currently managed solely with supportive therapy, which is directed towards maintenance of effective blood volume and electrolyte balance. Shock, cerebral edema,

TABLE 32.4 Selected Promising Treatment Options

Treatment option	Success	Issues/concerns
Antibody therapy	Efficacy in rodents and nonhuman primates	Escape mutants; genetic variability; antibody-dependent enhancement (ADE)
Antisense oligonucleotides		
Phosphorodiamidate morpholino oligonucleotides (PMOs)	Efficacy in rodents and nonhuman primates (NHPs) (prophylactic only)	Genetic variation; delivery
Small interfering RNAs (siRNAs)	Efficacy in rodents and NHPs	Genetic variation; delivery
Inflammatory modulators		
Type I interferons	Efficacy in rodents but not in NHPs	Manipulation of immune system
S-adenosylhomocysteine hydrolase (SAH) inhibitors	Efficacy in rodents but not in NHPs	Manipulation of immune system
Coagulation modulators		
Heparin sulfate	Efficacy in humans questionable; not tested in animals	Manipulation of coagulation
Tissue factor pathway inhibitors	Not tested in rodents; partial protection in NHPs	Manipulation of coagulation
Activated protein C	Not tested in rodents; partial protection in NHPs	Manipulation of coagulation
Postexposure vaccination		
Vesicular stomatitis virus (VSV)	Efficacy in rodents and NHPs	Efficacy dependent on species and treatment start

Note: Only approaches that have shown *in vivo* efficacy have been listed.

renal failure, coagulation disorders, and secondary bacterial infection may be life threatening and have to be managed. Antipyretics and pain medication should be provided as needed. At present, there is no proof that any strategy has been successful; however, detailed knowledge of filovirus replication, pathogenesis, and host responses to infections has steadily identified new targets for therapeutic intervention (Table 32.4). Although no single treatment is likely to be sufficiently potent to offset the severe and rapid progression of EHF and MHF, a combination of therapies (with different mechanistic actions) may be a more effective approach to treating infections. Slowing disease progression may provide enough time for the adaptive immune response to develop enough momentum to clear the infection.^{42,97,101,282}

Over the years, several experimental therapeutic approaches that target the virus or the host immune response have been evaluated in different animal models.^{30,42,97,282} The use of specific antisera as a therapy for filovirus infections (Table 32.4) has been investigated since their discovery,^{33,238} but their development has been complicated by lack of efficacy and reports on the potential of antibody-dependent enhancement (ADE) of infection as demonstrated *in vitro*^{388,394} but not yet confirmed *in vivo*.¹³² Convalescent blood and serum have been administered to human patients,^{87,293} but any beneficial results from these treatments are either unsupported or conflicting. Antibody therapy with equine anti-EBOV immunoglobulin has failed to protect nonhuman primates from fatal outcomes.^{206,284} However, more recently, the first successful IgG transfer that protected rhesus macaques from lethal MARV and EBOV challenge was reported,⁸² which might indicate that antibody therapy could be more beneficial. *In vitro* neutralizing EBOV GP-specific monoclonal antibodies generated from different species, including human, showed distinct protective and therapeutic properties in rodent and nonhuman primate models.^{277,308,311,325a,389,446} Although no definite therapeutic

conclusion can yet be drawn from the current studies, passively acquired antibodies can to a certain extent reduce the viral burden during infection, which could be useful in combination with other pharmaceutical agents.

Because filoviruses inhibit the expression of type I interferons (discussed earlier), treatment with exogenous IFN would seem to be an obvious therapeutic approach (Table 32.4). However, despite efficacy in the mouse model, IFN- α treatment was less effective in guinea pigs and failed to increase survival rate in nonhuman primates, despite a delay in disease onset, viremia, and death.²⁰⁴ The beneficial effect of S-adenosylhomocysteine hydrolase (SAH) inhibitors on EBOV infection in mice¹⁸⁵ has been partially associated with a mechanistically unexplained strong increase of IFN- α production. Therefore, improved formulations, selective use of IFN types and IFN- α subtypes, and the combination with other treatment options may be useful.

The viral transcription and replication machinery is an important antiviral target (Table 32.4). Unfortunately, ribavirin (1- β -D-ribofuranosyl-1,2,4-triazole-3-carboxamide), a broad-spectrum synthetic guanosine analog with virustatic activity against a number of RNA viruses including arenaviruses and bunyaviruses, has no *in vitro* or *in vivo* effect on filoviruses.^{184,190} Recent strategies to interfere with transcription and replication include antisense oligonucleotides, phosphorodiamidate morpholino oligomers (PMOs) and RNA interference (RNAi).^{90,116,136,142,387,431,433,434} These approaches are promising, but may be limited by sequence specificity (genetic variation of species), production (high costs) and the administration route (mainly intravenous).

Vaccine vectors based on recombinant vesicular stomatitis virus (VSV) expressing EBOV or MARV GP^{121,130} have shown remarkable utility when administered to nonhuman primates 30 minutes and up to 48 hours following lethal EBOV and MARV infection, respectively.^{71,99,129,133} This strategy was

used in a recent needle stick injury with high-risk exposure to ZEBOV. It is currently unclear whether the treatment prevented infection or the incident did not lead to infection, but there were no adverse effects noted with the administration of the vaccine vector.¹⁵⁸ Postexposure vaccination with VSV-based vectors is species specific due a lack of cross-protection among the various EBOV species.^{93,130}

The targeting of host gene products might also prove to be beneficial in treating filovirus disease. The production of TNF- α can develop into a deleterious host response during infection, and the therapeutic use of anti-TNF- α neutralizing antibodies has been partially successful in rodent models,^{189,190,191} but has not been evaluated in nonhuman primates. Furthermore, inhibitors of apoptosis of lymphocytes during EBOV infection^{134,177} might be a possible intervention strategy. There have been relatively few attempts to modulate the dysregulated cytokine/chemokine response that is a consistent feature of many VHFs. Treating MARV-infected guinea pigs with Desferal, an IL-1 and TNF- α antagonist, partially protected these animals.^{190,191} In another study, treating MARV-infected guinea pigs with IL-1 receptor antagonist (IL-1RA) or anti-TNF- α serum decreased the concentration of circulating TNF- α and protected 50% of the animals from lethal infection.¹⁸⁹

Coagulation abnormalities are a hallmark of filovirus infections and considered a key factor in pathogenesis. The nematode-derived anticoagulation protein (rNAPc2) was used to treat ZEBOV-infected nonhuman primates and resulted in 33% survival in an otherwise uniformly lethal animal model.¹³⁵ The same treatment has shown reduced efficacy when administered to animals infected with MARV, Angola strain, but other less virulent strains have not been tested yet¹²⁷ (Table 32.4). D-dimer formation has been identified as an early event during EBOV infection in nonhuman primates and could be used as a marker for treatment.¹³⁵ As rNAPc2 primarily targets signaling through the extrinsic blood coagulation pathway, additional benefits might be realized by using inhibitors of Factor X, targeting the common pathway, thereby blocking signaling through both the extrinsic and intrinsic blood coagulation pathways. A recent study showed that treatment of ZEBOV-infected nonhuman primates with recombinant human activated protein C resulted in partial protection consistent with survival seen with rNAPc2.¹⁷⁶ Both drugs have been approved for different applications in humans and could be more easily and safely considered under emergency use protocols.

Given the severe and rapid progression of filovirus infections, monotherapy is unlikely to be effective versus combination approaches that interfere with disease progression to allow innate and adaptive immune responses to overcome infection.^{42,101} Viremia levels below $1 \times 10^{4.5}$ pfu/mL are strongly associated with survival of patients and experimentally infected nonhuman primates.⁹⁷

Prophylaxis

Protective EBOV and MARV vaccines would be extremely valuable for at-risk medical personnel, first responders, military personnel, researchers, and populations affected during a filovirus outbreak. Attempts to produce vaccines from cell culture-derived filovirus particles (inactivated with formalin, heat, or gamma irradiation) have not been effective in stimulating protective immune responses.⁹³ More recently, vaccine development has concentrated on the use of subunit vaccines

based on a single, or combination of, viral structural proteins to induce protective immunity against an EBOV challenge. Aside from minor efforts to use the viral structural proteins VP24, VP30, VP35, and VP40 as immunogens, GP and to a lesser extent NP are the key viral proteins used for vaccination approaches. The following different delivery/expression systems have been evaluated in established animal models³⁰: naked DNA^{80,271,283,407,459,464}; virus-like particles (VLPs)^{382,385,386,427,429,430,432,437,466}; replication-deficient vectors such as adenovirus^{68,125,228,240,313,320,331,339,377,378,381,424,425,426,464}; Venezuelan equine encephalitis virus (VEEV) replicons^{178,242,324,325}; and replication-competent live attenuated vectors such as vaccinia virus,^{62,150} vesicular stomatitis virus (VSV),^{70,126,128,131,220,221} human parainfluenza virus type 3 (HPIV3),^{45,46,47,50} and New Castle disease virus (NDV).⁷⁷ Recently, a new concept based on replication-deficient ZEBOV (lacking VP35) generated through “reverse genetics” has shown promising protective efficacy in rodent models,¹⁶³ but remaining safety issues need to be addressed prior to generating proper vaccine candidates.

Most of the vaccine approaches showed protective efficacy in rodent models, but several failed to protect nonhuman primates.^{93,143,130} Currently, at least five different vaccine systems (based on adenovirus serotype 5 [Ad5], VEEV, VSV, HPIV3, and VLPs) have demonstrated complete protection against lethal filovirus infections in nonhuman primates, the gold standard animal model. Of those, the replication-deficient Ad5 system is the furthest developed platform and has already been in phase I clinical trials.²⁴⁰ This platform has been further developed by others using a multivalent adenovirus technology for the development of a panfilovirus vaccine that provides protection against several filovirus species.³⁸⁴ In addition, effective mucosal delivery seems possible. The Ad5 platform seems safe and robust but suffers from preexisting immunity in the world population and the recent failure in an AIDS/HIV trial.^{37,64} Preexisting immunity might be bypassed through mucosal delivery, which would also be beneficial for mass vaccination and for administration in rural Africa.^{68,313} The VLP platform, generated by co-expression of the viral proteins VP40, NP, and GP^{429,432} seems to best address safety issues but may require adjuvant and booster immunization for potent efficacy in nonhuman primates, which is less favorable for emergency use. Other issues are associated with the costs and production of the VLP-based vaccine compared to viral vector-based platforms.

Live attenuated recombinant vaccine vectors may be of advantage over nonreplicating vectors because of their ease in production and their more potent stimulation of innate and adaptive (humoral and cellular) immune responses. It would be difficult to ensure the safety of live attenuated EBOV and MARV strains, because of the high level biohazard of filoviruses. However, promising live attenuated filovirus vaccine vectors have recently been developed based on the backgrounds of VSV and HPIV3.^{93,124,130} The VSV-based vectors are more advanced and have demonstrated efficacy in nonhuman primate models.^{93,124,130} However, the vectors are associated with safety issues despite having a clean record in experimental animal models including immunocompromised animals.^{93,128,130,221} As with Ad5 and HPIV3 vectors, preexisting immunity is negligible for VSV. Both the HPIV and VSV vaccine platforms may have potential for needleless delivery.^{47,326} The VSV-based platform has the potential for a multivalent vaccine protecting against several species of EBOV and MARV¹³¹ and is the only

filovirus vaccine platform with postexposure efficacy in the nonhuman primate model.^{71,99,129,133}

It should be noted here that vaccine efforts for filoviruses have been largely based on ZEBOV and MARV strain Musoke immunogens. In particular, cross-species protection has only been achieved in a few attempts.^{92,93,131,175,278}

Despite largely good to excellent protective efficacy in animal models, correlates and mechanisms of protection have not been well defined for most of the vaccine candidates. Current data on antibody responses, T-cell proliferation, and CTL responses indicate that antibody and T-helper cell memory are essential for protection and that cell-mediated immunity, while possibly important, is not an absolute requirement. Total antibody response is thought to be a correlate for protection for filovirus vaccines.³⁷⁹

The *Paramyxoviridae* include some of the great and ubiquitous disease-causing viruses of humans and animals, including one of the most infectious viruses known (measles virus), some of the most prevalent viruses known (measles virus, parainfluenza viruses [PIVs], mumps virus, respiratory syncytial virus [RSV], and metapneumovirus), a virus that has been targeted by the World Health Organization for eradication (measles virus; however, to date, eradication has failed), a virus that has been eradicated (rinderpest virus), viruses that have a major economic impact on poultry rearing (Newcastle disease virus [NDV]), and many recently identified viruses (pinniped morbilliviruses, Hendra virus, Nipah virus, J virus and Beilong virus), some of which cause deadly diseases (Hendra and Nipah viruses). The *Paramyxoviridae* are enveloped negative-stranded RNA viruses that have special relationships with two other families of negative-strand RNA viruses, namely the *Orthomyxoviridae* (for the biological properties of the envelope glycoproteins) and the *Rhabdoviridae* (for the similarity of organization of the nonseg-

mented genome and its expression). The *Paramyxoviridae* are defined by having a protein (F) that causes viral–cell membrane fusion, in most cases at neutral pH. The genomic RNA of all negative-strand RNA viruses has to serve two functions: first as a template for synthesis of messenger RNAs (mRNAs) and second as a template for synthesis of the antigenome positive strand. Negative-strand RNA viruses encode and package their own RNA polymerase (RNAP); however, mRNAs are only synthesized once the virus has been uncoated in the infected cell. Viral replication occurs after synthesis of the mRNAs and requires the continuous synthesis of viral proteins. The newly synthesized antigenome positive strand serves as the template for further copies of the negative-strand genomic RNA.

CLASSIFICATION

The family *Paramyxoviridae* is classified into two subfamilies: the *Paramyxovirinae* and the *Pneumovirinae*. The *Paramyxovirinae* contains seven genera: *Respirovirus*, *Rubulavirus*, *Morbillivirus*, *Henipavirus*, *Aquaparamyxovirus*, *Avulavirus*, and *Ferlavirus*. The *Pneumovirinae* contains two genera *Pneumovirus* and *Metapneumovirus*. The classification is based on morphologic criteria, the organization of the genome, the biological activities of the proteins, and the sequence relationship of the encoded proteins now that all of the genome sequences have been obtained. The more recently identified tree shrew (*Tupaia*) paramyxovirus, J virus, Beilong virus, Salem virus, Menangle virus, Mossman virus, Fer-de-Lance virus, and Tioman virus have yet to be officially classified within the *Paramyxovirinae* by the International Committee on the Taxonomy of Viruses.

The morphologic distinguishing feature among enveloped viruses for the subfamily *Paramyxovirinae* is the size and shape of the nucleocapsids (diameter 18 nm, 1 μ m in length, a pitch of 5.5 nm), which have a left-handed helical symmetry. The biological criteria are (a) antigenic cross-reactivity between members of a genus and (b) the presence (*Respirovirus* and *Rubulavirus*) or absence (*Morbillivirus* and *Henipavirus*) of neuraminidase (NA) activity. In addition, the differing coding potentials of the *P* genes are considered, and there is the presence of an extra gene (*SH*) in some rubulaviruses as well as J virus and Beilong virus. The pneumoviruses can be distinguished from *Paramyxovirinae* morphologically, as they contain narrower nucleocapsids. In addition, the *Pneumovirinae* have major differences in the number of encoded proteins and an attachment protein that is very different from that of *Paramyxovirinae*. Examples of members of various genera are shown in Table 33.1.

TABLE 33.1 Examples of Members of the Family *Paramyxoviridae*

Family <i>Paramyxoviridae</i>
Subfamily <i>Paramyxovirinae</i>
Genus <i>Rubulavirus</i>
Mumps virus (Mu V)
Parainfluenza virus type 5 (previously called simian virus 5 [SV5] (PIV5))
Human parainfluenza virus type 2, types 4a and 4b (HPIV2/4a/4b)
Mapuera virus
Porcine rubulavirus (La-Piedad-Michoacan-Mexico virus)
Genus <i>Avulavirus</i>
Newcastle disease virus (avian paramyxovirus 1) (NDV)
Genus <i>Respirovirus</i>
Sendai virus (mouse parainfluenza virus type 1) (SeV)
Human parainfluenza virus type 1 and type 3 (HPIV1/3)
Bovine parainfluenza virus type 3 (bPIV3)
Genus <i>Henipaviruses</i>
Hendra virus (HeV)
Nipah virus (NiV)
Genus <i>Ferlavirus</i>
Fer-de-Lance virus (FDLV)
Genus <i>Aquaparamyxovirus</i>
Atlantic salmon paramyxovirus
Genus <i>Morbillivirus</i>
Measles virus (MeV)
Cetacean morbillivirus
Canine distemper virus (CDV)
Peste-des-petits-ruminants virus
Phocine distemper virus
Rinderpest virus
Subfamily <i>Pneumovirinae</i>
Genus <i>Pneumovirus</i>
Human respiratory syncytial virus A2, B1, S2 (HRSV)
Bovine respiratory syncytial virus (BRSV)
Pneumonia virus of mice (PVM)
Genus <i>Metapneumovirus</i>
Human metapneumovirus (HMPV)
Avian metapneumovirus
Unclassified paramyxoviruses
<i>Tupaia</i> paramyxovirus (TPMV)
Menangle virus (MenV)
Tioman virus (TiV)
Beilong virus
J virus
Mossman virus (MoV)
Salem virus (SaV)
Nariva virus

THE STRUCTURE AND REPLICATION STRATEGY OF THE *PARAMYXOVIRIDAE*

Paramyxoviruses contain nonsegmented single-stranded RNA genomes of negative polarity and replicate entirely in the cytoplasm. Their genomes are 15 to 19 kB in length, and the genomes contain 6 to 10 tandemly linked genes. A lipid envelope containing two surface glycoproteins (F and a second gly-

coprotein variously referred to as HN, or H or G) surrounds the virions. Inside the envelope lies a helical nucleocapsid core containing the RNA genome and the nucleocapsid (N), phospho- (P), and large (L) proteins, which initiate intracellular virus replication. Residing between the envelope and the core lies the viral matrix (M) protein that is important in virion architecture, and which is released from the core during virus entry. In addition to the genes encoding structural proteins, paramyxoviruses contain “accessory” genes that are found mostly as additional transcriptional units interspersed with the tandemly linked invariant genes. For the *Paramyxovirinae*, the accessory genes are found mostly as open reading frames (ORFs) that overlap within the *P* gene transcriptional unit.

Intracellular replication of paramyxoviruses begins with the viral RNA-dependent RNAP (minimally a homo-tetramer of P and a single L protein) transcribing the N-encapsidated genome RNA (N:RNA) into 5′ capped and 3′ polyadenylated mRNAs. The viral RNA-dependent polymerase (vRNAP) begins RNA synthesis at the 3′ end of the genome and transcribes the genes into mRNAs in a sequential (and polar) manner by terminating and reinitiating at each of the gene junctions. The junctions consist of a gene-end (GE) sequence, at which polyadenylation occurs by the reiterative synthesis of adenylates directed by a template of four to seven uridylates (followed by release of the mRNA), a short nontranscribed intergenic (IG) region, and a gene-start (GS) sequence that specifies mRNA initiation as well as capping. The vRNAP occasionally fails to reinitiate the downstream mRNA at each junction, leading to the loss of transcription of further downstream genes; hence, there is a gradient of mRNA synthesis that is inversely proportional to the distance of the gene from the 3′ end of the genome. After primary transcription and translation, when sufficient amounts of unassembled N protein are present, viral RNA synthesis becomes coupled to the concomitant encapsidation of the nascent [+] RNA chain. Under these conditions, vRNAP ignores all of the junctions (and editing sites) to produce an exact complementary antigenome chain in a fully assembled nucleocapsid.

VIRION STRUCTURE

The *Paramyxoviridae* contain a lipid bilayer envelope that is derived from the plasma membrane of the host cell in which the virus is grown.⁵⁹ *Paramyxoviridae* are generally spherical, 150 to 350 nm in diameter, but can be pleomorphic in shape, and filamentous forms can be observed. Inserted into the envelope are glycoprotein spikes that extend approximately 8 to 12 nm from the surface of the membrane, and that can be readily visualized by electron microscopy. Inside the viral membrane is the nucleocapsid core (sometimes referred to as the ribonucleoprotein [RNP] core) that contains the 15,000 to 19,000 nucleotide single-stranded RNA genome. Figure 33.1 shows a highly stylized schematic diagram of the virion. F and HN are trimers and tetramers, respectively. No attempt has been made to represent the real abundance of F, HN, SH, or N subunits in the virion. The pleomorphic nature of virus particles is illustrated in the electron micrograph in Figure 33.2, and a comparison of the RNPs of influenza virus, rabies virus, and Sendai virus is shown in Figure 33.3.

The helical nucleocapsid, rather than the free genome RNA, is the template for all RNA synthesis. For Sendai virus,

FIGURE 33.1. Schematic diagram of a paramyxovirus (not drawn to scale). The lipid bilayer is shown as the *gray concentric circle*, and underlying the lipid bilayer is the viral matrix protein shown as a *dark gray circle*. Inserted through the viral membrane are the hemagglutinin-neuraminidase (HN) attachment protein and the fusion (F) protein. The relative abundance of HN and F is not illustrated by the diagram. The small hydrophobic protein, SH, is found only in certain rubulaviruses, such as parainfluenza virus type 5 (PIV5). The HN protein is thought to have a stalk region and a globular head, and the F protein consists of two sulfide-linked chains F₁ and F₂. The HN protein is a tetramer, and the F protein a trimer. Inside the virus is the negative-strand virion RNA that is encapsidated with the nucleocapsid protein (N). Associated with the nucleocapsid are the L and P proteins, and together this complex has RNA-dependent RNA transcriptase activity (vRNAP). For the rubulaviruses, the cysteine-rich protein V is found as an internal component of the virion, whereas for other members of the family, the V protein is only found in virus-infected cells. The nature of possible interactions between the cytoplasmic tails of the glycoprotein spikes and the matrix protein, as well as the interactions between the matrix protein and the nucleocapsid, have not been fully elucidated, and no attempt has been made to illustrate them.

each nucleocapsid is composed of approximately 2,600 N, 300 P, and 50 L proteins.²¹⁴ The N and genome RNA together form a core structure, to which the P and L proteins are attached. This nucleocapsid core is remarkably stable, as it withstands the high salt and gravity forces of cesium chloride (CsCl) density gradient centrifugation. In the electron micrograph of nucleocapsids, the P and L proteins are not observed and have only been visualized with the aid of antibodies.³²⁷ Holo-nucleocapsids (N:RNA plus P and L) have the capacity to transcribe mRNAs *in vitro*, presumably mimicking primary transcription in infected cells, and they are thought to be the minimum unit of infectivity.

When negatively stained preparations of paramyxovirus nucleocapsids are viewed in the electron microscope, the most tightly coiled forms resemble the *Tobamovirus* tobacco mosaic virus (TMV)—a relatively rigid coiled rod 18 nm in diameter, with a central hollow core of 4 nm and a helical pitch of nearly 5 nm.^{68,115} Unlike TMV, however, in which the nucleocapsid must disassemble so its positive RNA genome can function as

FIGURE 33.2. Ultrastructure of parainfluenza virus type 5 (PIV5; formerly simian virus type 5 [SV5]) virions revealed by negative staining. **A:** Negatively stained PIV5 particle: The glycoprotein spikes on intact 150- to 300-nm virus particles can be observed (226,280 x). **B:** Negatively stained PIV5 nucleocapsid (74,570 x). **C:** Budding PIV5 virions particles from the surface of CV-1 cells: Colloidal gold staining of hemagglutinin-neuraminidase (HN) is shown (24,700 x). (Micrographs courtesy of George Leser, Northwestern University. Copyright © G. D. Park and R. A. Lamb, 2006.)

a template, paramyxovirus nucleocapsids function without disassembling their nucleocapsids.

Sendai virus nucleocapsids exist in several distinct morphologic states at normal salt concentration.^{101,156} The most prevalent form in negatively stained preparations is the most tightly coiled one, with a helical pitch of 5.3 nm. Two other forms—one with a slightly larger pitch of 6.8 nm and another with a much larger pitch of 37.5 nm—have also been noted.

FIGURE 33.3. Nucleocapsids of negative-strand RNA viruses. Electron micrographs of the nucleocapsids of three negative-strand RNA viruses, negatively stained with 1% sodium silicotungstate. **Top:** Ribonucleoprotein particles of influenza virus with a stoichiometry of 24 nucleotides per NP monomer. **Middle:** Nucleocapsids of rabies virus with a stoichiometry of 9 nucleotides per N monomer. **Bottom:** Nucleocapsids of Sendai virus with a stoichiometry of 6 nucleotides per N monomer. All micrographs have the same magnification; bar = 100 nm. (Micrographs courtesy of Rob Ruigrok, EMBL, Grenoble, France.)

The fact that no structures of intermediate pitch have been found indicates that these are distinct states. It is thought that the template is copied without dissociation of N protein from the nucleocapsid and the uncoiling of the nucleocapsid may be necessary for the polymerase to gain access to the RNA bases. It is possible that the vRNAP traverses the nucleocapsid template by uncoiling the helix in front of it and recoiling it once the polymerase has passed a given position, much the same as cellular RNAP generates its template “bubble” in traversing double-stranded DNA (dsDNA).

As expected, the diameter of the nucleocapsid decreases as the pitch increases and the nucleocapsid lengthens; for Sendai virus, the diameter is 3.5 nm less for the 6.8 nm form than for the 5.3 nm pitch form. These latter values are very similar to those of *Pneumovirus* nucleocapsids, which also have a pitch of 7 nm. As discussed earlier, these differences in nucleocapsid morphology are used to distinguish the different *Paramyxoviridae*; however, they probably relate mainly to which form predominates in negatively stained preparations.

THE PARAMYXOVIRIDAE GENOMES AND THEIR ENCODED PROTEINS

The complete genome sequence for all known members of the *Paramyxoviridae* has been obtained (available at <http://www.ncbi.nlm.nih.gov/>). The 15,000 to 19,000 nucleotide genomic RNA contain a 3′ extracistronic region of approximately 50 nucleotides known as the leader and a 5′ extracistronic region of 50 to 161 nucleotides known as the trailer (or [–] leader). These control regions are essential for transcription and replication, and flank the six genes (seven for certain rubulaviruses and eight to ten for pneumoviruses). (Note: By the convention used for paramyxoviruses, the term *gene* refers to the genome sequence encoding a single mRNA, even if that mRNA contains more than one ORF and encodes more than one protein). The coding capacity of the genome of *Paramyxovirinae* is extended by the use of overlapping ORFs in the P gene. The gene order of a representative member of each subfamily is shown in Figure 33.4. At the beginning and end of each gene are conserved transcriptional control sequences that are copied into mRNA. Between the gene boundaries are intergenic regions (Fig. 33.5). These are precisely three nucleotides long for the respiroviruses and morbilliviruses but are quite variable in length for the rubulaviruses (1–47 nucleotides) and pneumoviruses (1–56 nucleotides) (see Fig. 33.5).

The Nucleocapsid Protein

The nucleocapsid (N) protein is present as the first transcribed gene in the viral genome for all paramyxoviruses except the pneumoviruses and ranges in size from 489 to 553 amino acids (molecular weight ~53–57 kDa). N is an RNA-binding protein that coats full-length viral negative sense genomic and positive sense antigenomic RNAs to form the helical nucleocapsid template, which is the only biologically active form of these viral RNAs. Electron microscopy and three-dimensional image reconstruction for Sendai virus nucleocapsids reveals that N binds approximately six consecutive nucleotides and 13 N subunits constitute each turn of the nucleocapsid helix.¹⁰¹ In general, these parameters apply to other paramyxovirus nucleocapsids as well, although there can be slight differences in the number of N subunits per helix turn and in the pitch of the helix.¹⁵ The binding of N to RNA to form a helical structure is thought to serve several functions, including protection from nuclease digestion, minimizing the annealing of mRNA to complementary genomic RNA, alignment of distal RNA segments to create a functional 3′-end promoter, and most likely providing interaction sites for assembly of progeny nucleocapsids into budding virions.

Expression of paramyxovirus N proteins in the absence of other viral components results in the formation of nucleocapsid-like structures, suggesting that N has inherent self-assembly properties and that N–N interactions drive nucleocapsid assembly.^{116,277,287} Biochemical and mutational studies have shown that the N protein can be generally divided into two main structural regions: Ncore, an N-terminal domain representing approximately three-fourths of the protein and is conserved in sequence among related viruses, and Ntail, a C-terminal nonconserved acidic domain. Approximately 400 residues of the Sendai virus Ncore are essential for self-assembly, RNA binding, and activity in RNA replication.⁷⁶

FIGURE 33.4. Genetic map of a typical member of six genera of the *Paramyxoviridae*. The gene sizes are shown as boxes that are drawn to approximate scale, with 3'-leader and 5'-trailer regions indicated for Sendai virus only. Gene boundaries are shown by thin horizontal lines. Note that the beginning of the human respiratory syncytial virus *L* gene overlaps the end of the *M2* gene by 68 nucleotides, whereas human metapneumoviruses do not have an *L*-gene overlap. For J virus, X denotes an internal open reading frame in the *G* gene of unknown function.

FIGURE 33.5. Schematic diagram of a paramyxovirus genome with the transcriptional gene-end, intergenic, and transcription gene-start sequences. The positions of the extragenic 3'-terminal leader, 5'-terminal trailer, and gene junctions are shown as thin horizontal lines. The conserved gene-end (open triangle) and gene-start (rightward arrow) transcription regulatory sequences at the boundaries between genes are indicated. Consensus sequences for the gene-end, intergenic, and gene-start regions of representative viruses are listed as negative sense genomic RNA. Nucleotides that are strictly conserved at each viral junction are shown as capital letters; nucleotides that are mostly conserved (3/6 junctions or better) are shown in lowercase letters. SeV, Sendai virus; MeV, measles virus; NiV, Nipah virus; PIV5, parainfluenza virus 5; TiV, Tioman virus; RSV, respiratory syncytial virus.

For RSV, the N-terminal 92 residues are sufficient for assembly with RNA.²⁷¹ A central region of Ncore that is highly conserved for all members of the *Paramyxovirinae* (residues 258–369 for Sendai virus) contains an F-X4-Y-X3- ϕ -S- ϕ -A-M motif (where X is any residue and ϕ is an aromatic amino acid). This region is essential for self-assembly of N with RNA²⁷⁶ and may be involved in N–N or N–RNA interactions.

The C-terminal Ntail region is less well conserved among related paramyxoviruses. Treatment of purified nucleocapsids with trypsin removes a portion of the C-terminal Ntail to yield a more rigid structure,¹⁵⁵ suggesting that this domain may confer flexibility in the coiling of the native nucleocapsid. In contrast to the essential role of the N-terminal Ncore in all N functions, the C-terminal Ntail (124 residues for Sendai virus N) is dispensable for binding RNA and for assembly of newly synthesized N–RNA complexes during replication of defective interfering particle RNAs.⁷⁶ However, nucleocapsids that are assembled with N that lacks this C-terminal Ntail are not functional as templates for the viral RNAP.⁷⁶ Structural studies have shown that the C-terminal Ntail is intrinsically disordered,²⁶ consistent with a proposed role for this domain in multiple protein–protein interactions. One of these essential interactions with P protein is thought to tether the L–P polymerase complex to the nucleocapsid template.³⁷ For example, the measles virus C-terminal Ntail has been shown to interact with a C-terminal domain of the P protein, undergoing an induced folding in some parts of this N segment.^{26,186} In the case of measles virus, Ntail has also been shown to bind to the cellular chaperone protein Hsp72⁴⁵⁵—an interaction that could influence nucleocapsid morphologies and the synthesis of viral RNAs.⁴⁵⁵

The paramyxovirus nucleocapsid protein is an unusual RNA-binding protein, as it has an overall acidic charge (net charge of –7 to –12, with exception of mumps virus [+2]) and does not contain conventional RNA-binding motifs that are

typically found on cellular RNA-binding proteins. The interactions of N with RNA are remarkably stable, and nucleocapsid-associated RNA is protected from nucleases even at very high salt concentrations, or when the hypersensitive C-terminal Ntail is removed by protease digestion.¹⁵⁵ N binding to RNA is thought to be independent of nucleotide sequence and, through interactions with the phosphodiester backbone,¹⁸¹ a mechanism that would leave the nucleoside bases accessible to the viral RNAP during RNA synthesis. The Sendai virus nucleocapsid-associated RNA shows hyperreactivity to chemical treatment at cytidine residues predicted to be at positions one and six of a hexamer of nucleotides.¹⁸¹ Together with the finding that the Sendai virus N protein binds six nucleotides,¹⁰¹ these results have led to the proposal that the accessibility of the viral RNAP to bases within the nucleocapsid-associated genomic RNA may be controlled by their position within a hexamer of N-bound nucleotides.^{181,203}

N protein exists in at least two forms in infected cells: one stably associated with RNA in a nucleocapsid structure and a second unassembled soluble form termed N⁰. This latter form of N has been found to be associated with P in several viruses, including Sendai virus,¹⁶⁹ PIV5 (formerly known as simian virus 5 [SV5]),³³¹ measles virus,³⁷⁹ and RSV.¹²¹ N⁰ is thought to be the functional form of N that encapsidates the nascent RNA strand during genome and antigenome replication.^{78,169} N-terminal regions of Ncore are important for formation of the N⁰–P complex,¹⁶⁶ and these domains are distinct from those involved in binding of P to N in the assembled nucleocapsid.

The P Gene and Its Encoded Proteins

The *Paramyxovirinae* P gene is a remarkable example of exploiting the coding capacity within a viral gene. The Sendai virus P/V/C gene is the most diverse of the paramyxovirus P genes,

directing the expression of at least seven polypeptides, including the P, V, W, C, Y1, and Y2 proteins. Whereas other paramyxoviruses express fewer proteins from the *P/V/C* gene than Sendai virus, the *P* gene always produces more than one polypeptide species (Table 33.2). Expression of *P/V/C* proteins can involve two main mechanisms, with members of a paramyxovirus genus having a characteristic combination of these expression strategies. The first expression mechanism, which produces the P, V, and W/I/D proteins, has been termed *RNA editing* or pseudotemplated addition of nucleotides.^{307,408,419} This mechanism involves the production of mRNAs whose ORFs are altered by insertion of G residues at a specific position in the mRNA. As described later, the second expression mechanism involves ribosome initiation at alternative translation codons and produces the family of C proteins.

The P and V proteins, as well as virus-specific proteins variously referred to as W, I, and D, are produced as a co-N-terminal nested set of proteins. These polypeptides are translation products from distinct mRNAs that differ only by inserted G nucleotides that shift the translational reading frame at the site of insertion. As shown in Figure 33.6, the *P* gene of the respiro-,

morbilli-, and henipaviruses codes for a long N-terminal ORF shared by all three proteins and three shorter ORFs starting at approximately base 400 in the mRNA. During transcription of the nucleocapsid template, the viral RNAP is directed to make an accurate copy of the *P* gene template or to insert one or two G residues at a precise site in the nascent mRNA. The result is that the accurate transcription product encodes the full-length P ORF, whereas the mRNAs with insertions of +1G and +2G have a shift in the translational ORF such that the 5' end P ORF is fused at the site of insertion in the mRNA coding sequence to a more 3' ORF encoding V (+1G) or W (+2G). Thus, the P, V, and W/I/D proteins that are produced as a result of RNA editing share a common N-terminal region but differ in their C-terminal regions starting at the site of G insertion.

All viruses of the *Paramyxovirinae* (with the exception of human parainfluenza virus type 1 [HPIV1])²⁵⁰ encode a characteristic editing site in the *P* gene, and the number of inserted G residues, as well as the frequency of inserting G nucleotides, is determined by sequences surrounding and within the editing site. For example, Sendai virus encodes the P protein as the translation product from the unedited mRNA (+0 G; see Fig. 33.6). The V

FIGURE 33.6. Schematic diagram of translational open reading frames (ORFs) generated by RNA editing during *P* gene transcription for representative paramyxoviruses. Antigenome ORFs, which span the editing site in the *P* gene, are indicated at the top by boxes. The shared N-terminal ORF is shown as a white box. The RNA editing site, at which nontemplated nucleotides are added to the messenger RNA (mRNA) is indicated by the vertical line. At the bottom, RNA transcripts are shown to contain insertions of zero, one, or two G residues at the editing site, with shaded boxes indicating unique C-terminal ORFs fused to the common N-terminal ORF shown in white. For the respiro-, morbilli-, avula-, and henipaviruses, the mRNA for the P protein is transcribed faithfully (unedited) from the viral genome and is shown as a white box fused to a black box. Transcriptional RNA editing with the addition of one G nucleotide at the editing site produces an mRNA that encodes the V protein, in which the common N-terminal domain shown in white is fused to a different ORF. Addition of two G nucleotides at the editing site produces an mRNA that encodes the W or D or I proteins (depending on the virus). For rubulaviruses, the unedited mRNA encodes the V protein, the addition of either one or four G nucleotides produces mRNA encoding the W or I protein, and the addition of two G nucleotides produces the mRNA encoding the P protein. The cysteine-rich domain of the V protein is indicated by a striped box.

Insertion of G residues into *P* gene mRNA transcripts is a co-transcriptional event catalyzed by the vRNAP⁴¹⁹ and is usually limited to insertions of between 0 and 2 nucleotides, depending on the virus. Human and bovine parainfluenza virus type 3 (HPIV3 and BPIV3) are exceptions to this general rule, and mRNAs with one to six inserted G residues are almost equally abundant.¹²⁰

The P protein is the only *P/V/C* gene product that is essential for viral RNA synthesis.⁷⁸ P is generally 400 to 600 amino acids long and is heavily phosphorylated at serine and threonine residues, predominantly within the N-terminal region. P protein contains regions of high intrinsic disorder,²⁵ consistent with the requirement for interacting with multiple partners during the viral growth cycle. P is an essential component of both the vRNAP enzyme¹⁴¹ and the N⁰ nascent chain assembly complex that functions to encapsidate RNA during replication.¹⁶⁹ Extensive mutational analyses have identified distinct modular C- and N-terminal domains within the P protein that play essential roles as a polymerase cofactor and in nascent chain assembly, respectively.

The C-terminal polymerase cofactor module is relatively well conserved in predicted secondary structure for all viruses of the *Paramyxovirinae*, and all P proteins carry this essential module as the C-terminal segment of fusion protein with the shared P/V domain; this module is never naturally expressed by itself. The P protein C-terminal region contains domains for P-P multimerization, for interactions with L protein, and for binding to

the N:RNA template. P protein functions as a multimer, and structural analysis suggests that the Sendai virus P protein is a tetramer.⁴⁰² For Sendai virus, the P-carboxy region is sufficient for catalyzing viral RNA synthesis, as this protein fragment by itself (residues 325–568) can substitute for intact P protein in all aspects of mRNA transcription.⁷⁹ Although the L protein is thought to contain all vRNAP catalytic activities, L binds to the nucleocapsid template via the P protein.¹⁶⁹ This P–L interaction requires a domain in P that maps to the C-terminal end of the coiled-coil P–P multimerization region.^{32,80} At the end of the C-terminal domain, P also contains a region that binds to the N:RNA template,^{32,80} providing the bridge to link L with the N:RNA template. In the case of Sendai virus, structural data indicate that this C-terminal region of P binds through weak hydrophobic interactions to the C-terminal tail of N, inducing folding of the intrinsically disordered Ntail.²³² The ability of P and Ntail to form transient weak interactions between intrinsically disordered domains may be important for the dynamic functions of P during movement of the viral RNAP across the N:RNA template or in the flexibility of the nucleocapsid template.^{17,25,200}

In contrast to viral transcription, genome replication requires an N-terminal region of P (defined by deletion of Sendai virus residues 33–41). A short segment of the P protein N-terminal domain is thought to facilitate interactions with unassembled N⁰ to prevent N aggregation and to ensure specificity in assembly.^{78,169} The rest of the N-terminal domain of P protein is apparently dispensable for genome RNA synthesis and assembly, as a P protein in which residues 78 through 324 have been deleted is still active for minigenome replication in transfected cells.⁷⁴

The V protein is an approximately 25- to 30-kDa polypeptide that shares an N-terminal domain with the P protein but has a distinct C-terminal domain as a result of RNA editing.^{48,303,408,419} The C-terminal V-specific domain is highly conserved among related paramyxoviruses (Fig. 33.7), with invariantly

FIGURE 33.7. Amino acid sequence alignment of the conserved cysteine-rich C-terminal region of selected paramyxovirus V proteins. Numbers indicate the amino acid position within the respective proteins. Positions of the conserved histidine and seven conserved cysteine residues that are involved in coordinating Zn^{2+} are indicated by *bold lettering*. Additional areas of sequence identity are *shaded*.

FIGURE 33.8. Atomic structure of the parainfluenza virus type 5 (PIV5) V protein in complex with damage-specific DNA-binding protein 1 (DDB1). The PIV5 V protein binds to DDB1, which adopts a four-domain structure consisting of a three-propeller cluster and a helical C-terminal domain. **A:** Overall view of the DDB1-simian virus 5 (SV5)-V complex with DDB1 in blue and the PIV5 (SV5) V protein in red. The zinc ions in SV5-V are shown as orange spheres. The four DDB1 domains are labeled BPA, BPB, BPC, and CTD. The longest dimension of the complex is indicated. **B:** The PIV5 (SV5) V protein adopts a bipartite structure upon interacting with the DDB1 BPC domain. DDB1 and SV5-V are shown in surface and ribbon representation, respectively. The N-terminal part of the V protein, which is also found in the viral P protein, is colored in red. The rest of the V protein, including the zinc-binding sequence, is colored in gray. **C:** A novel zinc-finger fold found in the SV5-V protein. (Adapted from Li T, Chen X, Garbutt KC, et al. Structure of DDB1 in complex with a paramyxovirus V protein: Viral hijack of a propeller cluster in ubiquitin ligase. *Cell* 2006;124:105–117.)

spaced histidine and cysteine residues forming a novel domain that binds two zinc molecules per V protein.^{118,225,231,304} Despite the high level of intracellular synthesis, paramyxovirus particles typically contain little V protein,³⁰⁴ and the degree of incorporation of V into virions varies among paramyxoviruses.^{75,431}

V protein plays several important roles in the virus replication cycle, as evidenced by recombinant viruses that have been engineered to disrupt expression of the V protein Cys-rich domain.^{12,153,191,412} In many cases, these mutant viruses display an elevated RNA synthesis phenotype, although they generally grow well in many tissue culture cell lines.^{82,192} However, in many cases, these viruses are severely attenuated for growth *in vivo* or are cleared more rapidly than wild-type viruses from lungs of infected animals.^{94,192,418} These results suggest that V is an accessory protein that plays a role in viral pathogenesis, perhaps involving a counteracting of host cell antiviral responses that occur early after infection and that can lead to enhanced clearance of virus.

V protein has also been shown to inhibit viral RNA synthesis in transfection experiments involving model RNA genomes.^{78,168,229} Recombinant viruses that are engineered with V protein mutations often show increased viral RNA synthesis.^{81,191,360,412,430} This has led to the proposal that V protein serves as a negative regulator of viral RNA synthesis. V protein shares the amino-terminal domain of P protein that can interact with N⁰ to form the assembly competent P-N⁰. Thus, the mechanism of V inhibition may involve interactions with N that result in a form of a V-N⁰ complex that is not competent to function during the RNA encapsidation step of replication. This V-N⁰ interaction has been detected

in the case of PIV5, Sendai virus, and measles virus,^{168,331,412} and a model whereby V and P compete for soluble N⁰ has been proposed.^{78,168} The V protein is also capable of binding RNA,²²⁶ and it has been proposed that this function is involved in inhibiting RNA synthesis for the Sendai virus V protein.³⁰⁰

In addition to binding viral components, V protein also has been detected in interactions with cellular proteins. For several paramyxoviruses, V protein interacts in the cytoplasm with the cellular damage-specific DNA-binding protein 1 (DDB1).^{4,227} In the case of the PIV5 V protein, interaction with DDB1 is important for the function of blocking signaling through the type I interferon pathway (see later discussion). Interaction of V with DDB1 and the ability of V to inhibit host cell antiviral responses depends on the C-terminal Cys-rich domain but can also be disrupted by alterations to the common N-terminal P/V region.^{4,227} The structural analysis of PIV5 V protein complexed with DDB1 shows that V protein has a bi-partite structure,²²⁵ with a core domain built around a central seven-stranded β sheet, which is in turn sandwiched between one α helix and two long loops (see Fig. 33.8). The unique C-terminal domain forms the middle two β sheets and part of the central core, and this structure is anchored through the Cys-rich zinc-binding region. Thus, despite sharing a 164 amino acid N-terminal domain, the PIV5 P and V proteins can adopt very different structures owing to the unique properties of the C-terminal Cys-rich region. V protein from several paramyxoviruses has been shown to interact through the Cys-rich domain with the cellular protein MDA-5, an IFN-inducible host cell DEXD/H box helicase that is involved in signaling to initiate host cell antiviral responses.

The W/D/I Proteins

The W and D ORFs of respiro-, morbilli- and henipaviruses are expressed from mRNAs with two inserted G residues (see Fig. 33.6). For most of these viruses, the insertion of two G residues into the mRNA is relatively rare, and the ORF is closed by a stop codon shortly after the editing site, resulting in the ORF for the W protein. Thus, the W protein is essentially a truncated P protein, containing the N-terminal N⁰ assembly module of the P protein alone. W protein is abundantly expressed in Sendai virus-infected cells⁷³ and has been found to interact with unassembled N⁰, suggesting an inhibitory role in viral RNA synthesis.¹⁶⁸ In the case of BPIV3 and HPIV3, the +2 ORF extends for 131 residues from the editing site, and the protein that links the amino-terminal P domain to this ORF is called *D protein*.¹²⁰ The *Rubulavirus* I protein is generated when the upstream N-terminal P region is fused to a downstream ORF by the insertion of either one or four G residues during RNA editing.^{303,408} The role that the W/D/I proteins play in the viral growth cycle has not been established.

The C Proteins

In addition to RNA editing, some paramyxoviruses use a second mechanism to express *P* gene polypeptides that involves the use of alternative translation initiation codons to yield the C proteins (Fig. 33.9). The Sendai virus C', C, Y1, and Y2 proteins comprise a nested set of carboxy-co-terminal polypeptides that range in size from 175 to 215 residues. These proteins are expressed independently from a P/V mRNA through the use of alternative start codons (Fig. 33.9), with the C protein ORF being in the +1 reading frame relative to the P ORF. The C'

and C proteins are translated by a leaky scanning mechanism, being initiated at an unconventional ACG triplet at base 81 and AUG at base 114, respectively.⁷⁷ By contrast, translation of the Y1 and Y2 proteins occurs through a scanning-independent ribosome shunting mechanism that is directed by a 5' noncoding RNA segment, resulting in ribosomes initiating at AUG codon bases 183 and 201, respectively. Translation of each of the C', C, Y1, and Y2 ORFs is initiated at a different site, although translation is terminated at the same downstream stop codon; thus, these proteins share a common C-terminal region. The C protein is abundantly expressed in infected cells at levels higher than C', Y1, and Y2; however, virions contain only very low levels of these polypeptides.²¹⁷ Morbilliviruses express one C protein,¹³ as do the henipaviruses,⁴²⁷ whereas the respiroviruses such as Sendai virus and HPIV1 express all four C', C, Y1, and Y2 polypeptides.¹²⁸ Rubula- and avulaviruses do not express C proteins (see Table 33.2).

C proteins are small basic polypeptides that play multiple functions in the viral growth cycle, being involved in the control of viral RNA synthesis, counteracting host cell antiviral pathways, and facilitating release of virus from infected cells. Although nonessential for infectivity, Sendai virus mutants engineered to express only a subset of C proteins or lacking expression of all four proteins show defects in virus growth.²⁰⁹ The C proteins have been shown to inhibit mRNA transcription and suppress RNA replication in a promoter-specific manner.^{193,238,399} Consistent with this, viral mutants that are engineered to lack C protein expression show elevated synthesis of viral mRNA and protein.¹⁴⁷ The inhibition of RNA synthesis by C proteins correlates with the ability to bind to the

FIGURE 33.9. Representation of the Sendai virus P messenger RNA (mRNA) to illustrate the mechanisms of producing P, V, and C proteins. The position of four unique initiation codons for the C', C, Y1, and Y2 open reading frames (ORFs) are shown above the horizontal black line representing the *P* gene mRNA. The position of the common initiation codon for the P, V, and W ORFs at base 104 is shown below the mRNA. The gray cylinder indicates the V protein Cys-rich C-terminal domain, which is fused to the shared P N-terminal domain by addition of a G residue during viral transcription; the black cylinder indicates the short W domain, which is accessed by insertion of two G residues. Numbers denote the amino acids contained within each polypeptide chain. Note that the initiation codon for C' is ACG.

L subunit of the viral polymerase,¹⁷⁰ and in the case of Sendai virus, naturally occurring variant C proteins can have differential effects on inhibition of virus RNA synthesis.¹⁰

The role of paramyxovirus C proteins in pathogenesis and in counteracting host cell IFN responses is best understood in the cases of Sendai virus and measles virus. For Sendai virus, the C', C, Y1, and Y2 proteins can antagonize IFN signaling when assayed in stably transfected HeLa cells¹⁹³; however, there may be more subtle differences in the functions of each polypeptide in the context of viral mutants.¹²⁴ In the case of measles virus, recombinant viruses defective for C protein expression grow well in certain culture cells but are defective for growth in peripheral blood mononuclear cells¹⁰⁴ and are less virulent *in vivo*.³¹⁰ Changes in pathogenesis of C-mutant viruses may be related to the ability of the C proteins to inhibit type I IFN responses.³⁶⁸ This proposal is further supported by a naturally occurring mutation in the Sendai virus C protein (phenylalanine 170 to serine) that eliminates the ability of C protein to block IFN signaling,¹²⁴ and a mutant Sendai virus harboring this altered C protein is attenuated for growth in mice. The mechanism by which C proteins attenuate IFN signaling has not been elicited but may involve binding of C to STAT1¹²⁴ or altering STAT1 phosphorylation patterns.²⁰⁵

An additional role for C proteins in virus release became evident with the analysis of mutant Sendai virus that cannot express any of the four C proteins.²⁰⁹ Whereas viral RNA and protein synthesis was high for this mutant virus, production of infectious virions was low, and heterogeneous noninfectious particles were produced.¹⁴⁷ C protein expression enhances release of virus-like particles (VLPs), possibly through interactions with AIP1/Alix—a cellular protein involved in apoptosis and endosomal trafficking.³⁴⁷

The Large Protein

The large (L) protein is an essential subunit of the paramyxovirus RNAP. Consistent with a catalytic role in viral RNA synthesis, the L protein is invariably encoded as the most promoter-distal gene in the paramyxovirus genome (see Fig. 33.4). L protein is generally found in only very low amounts in infected cells or associated with nucleocapsids and virions.²¹⁴ A paramyxovirus particle typically contains only about 50 copies of L,²¹⁴ where it is found on the nucleocapsid in clusters that co-localize with P protein.³²⁷ L is thought to possess all of the enzymatic activities needed for synthesis of functional viral mRNA, including nucleotide polymerization as well as 5'-end capping and methylation and 3'-end polyadenylation of mRNAs.^{137,158,289} Polyadenylation of viral mRNAs occurs co-transcriptionally, where L is thought to add poly A tails to nascent viral mRNAs through a mechanism that involves stuttering at a stretch of template U residues at the end of each viral gene (see Fig. 33.5). L protein is also responsible for the replication of viral genomic and antigenomic RNA; however, this form of RNA synthesis differs from mRNA transcription by having a strict requirement for soluble N⁰ to allow encapsidation of the nascent genomic RNA.^{139,169}

The paramyxovirus L protein is generally approximately 2,200 amino acids in length (~250 kDa). Although the N- and C-terminal regions of the L proteins are diverse, sequence comparisons among L proteins have identified six highly conserved domains (I–VI) near the middle of the polypeptide. It was originally proposed that these domains may be individually

responsible for each of the multiple L functions.³¹⁹ Domain II is proposed to be an RNA-binding domain owing to the high net positive charge. In domain III, mutational analyses are consistent with the proposal of a conserved GDNQ motif as the active site for nucleotide polymerization.²³⁷ Based on sequence homologies, domain VI of the rhabdovirus L protein has been implicated in playing a major role in 5' cap formation, perhaps as a methyltransferase domain.^{114,319} The precise roles of the remaining domains I, IV, and V in individual steps of RNAP activity are not clear; however, for Sendai virus, mutations in some of these domains result in L proteins that can transcribe viral mRNA but are defective in RNA replication.^{56,113} In the case of the L proteins of Sendai virus and rinderpest virus, sequence alignment has identified nonconserved hinge regions that can be modified by insertions of green fluorescent protein (GFP), and remarkably, viable recombinant viruses encoding these L-GFP hybrid proteins have been isolated and used to identify sites of L localization during infection.^{35,92}

L protein activity in RNA synthesis highly depends on protein–protein interactions, involving self-assembly as well as binding to other viral and cellular proteins. Biochemical evidence and genetic complementation studies indicate that the Sendai and measles virus L proteins function as homomultimers that interact through an N-terminal self-assembly domain.^{54,376} L also binds to the viral P protein—an interaction that is essential for formation of the active enzyme complex and can lead to enhanced stability of L.^{141,169} L–P interaction domains generally map to an N-terminal domain of L that is distinct from the L–L assembly domain.¹⁶⁵ Within the L–P complex, P protein serves as the bridge to link the L polymerase to the nucleocapsid template.^{80,169} In addition to L–L and L–P interactions, L protein also interacts with host cell proteins.^{269,375} In the case of measles virus and Sendai virus, L interactions with tubulin are thought to promote L activity.²⁶⁹ Other cellular proteins have also been shown to promote viral RNA synthesis (e.g., β -catenin for HPIV3),²² although the precise role that these proteins play in viral RNA synthesis has not been determined.

Whereas interactions of L with P are generally thought to promote activity, L protein can also interact with other viral components that inhibit the vRNAP. For both rinderpest virus and Sendai virus, L protein has been found to bind the viral C proteins.^{170,390} The Sendai virus L–C interactions are through a domain of L that maps to the first 895 residues (domains I–III),¹⁷⁰ and this binding correlates with inhibition of RNA synthesis.¹³⁸ Other proteins encoded in the viral *P/V/C* gene (C', Y1, and Y2) also interact with L and inhibit defective interfering RNA synthesis *in vitro*¹³⁸ and *in vivo*.¹⁹³

The Matrix Protein

The paramyxovirus matrix (M) protein is the most abundant protein in the virion. The M proteins contain 341 to 375 residues (M_r ~38,500–41,500), are quite basic proteins (net charge at neutral pH of +14 to +17), and are somewhat hydrophobic, although there are no domains of sufficient length to span a lipid bilayer. In electron micrographs of virions, an electron-dense layer is observed underlying the viral lipid bilayer, and this is thought to represent the location of this protein. Fractionation studies of virions indicate that the M protein is peripherally associated with membranes and is not an intrinsic membrane protein. Reconstitution studies of purified

FIGURE 33.10. Three-dimensional structure of the RSV M protein. The crystal structure of M (resolution 1.6 Å) shows two domains composed largely of β -sheets. **A:** Divergent (wall-eyed) stereoview of M colored according to domain with the linker shown in cyan, the N-terminal domain in blue, and the C-terminal domain in red. Residue R254 is shown in ball-and-stick representation. **B:** A topology diagram of the protein. The linker between the N- and C-terminal domains is shown in magenta. Residues (numbers refer to Met as +1) in β -sheets are represented by broad arrows and helices as cylinders. **C:** Electrostatic surface potential (calculated with APBS) for M, presented in a color range from red to blue (−5 to +5 kT/e); uncharged residues are uncolored. (From Money VA, McPhee HK, Mosely JA, et al. Surface features of a Mononegavirales matrix protein indicate sites of membrane interaction. *Proc Natl Acad Sci U S A* 2009;106:4441–4446.)

M protein and fractionation studies of infected cells indicate that the M protein can associate with membranes.^{105,212,280}

As a purified protein, the Sendai virus M protein can self-associate and form two-dimensional paracrystalline arrays (sheets and tubes) in low salt conditions.^{7,157} There is a paracrystalline array of identical periodicity at the inner surface of the plasma membrane of infected cells when examined by freeze-fracture techniques in the electron microscopy.⁷ In addition, the M protein is associated with nucleocapsids.³⁸⁶ As of January 2011 the only atomic structure of M to be obtained is that of RSV M.²⁶⁴ It shows that the protein has extensive β -sheets and a continuously charged region covering approximately 600 Å, which probably interacts with a negatively charged surface on the RNP (Fig. 33.10). Genetically engineered recombinant measles virus and PIV5 that lack glycoprotein cytoplasmic tails show a subcellular redistribution of the matrix protein,^{46,357} which implies that there is an interaction of the F and HN cytoplasmic tails with the M protein. Thus, the M protein is considered to be the central organizer of viral morphogenesis interacting with the cytoplasmic tails of the integral membrane proteins, the lipid bilayer, and the nucleocapsids. The self-association of M and its

contact with the nucleocapsid may be the driving force in forming a budding virus particle.³¹¹ The relative abundance of basic residues in the M protein may reflect their importance in ionic interactions with the acidic N proteins.

For several enveloped viruses, it has been shown that budding occurs by using components of the endosomal sorting complexes required for transport (ESCRTs)—proteins involved in multivesiculate body formation. Protein–protein interaction domains called *late domains* have been identified in the matrix proteins of several viruses; for the paramyxoviruses, a late domain has been identified in PIV5 M protein.³⁵⁸ This topic is discussed further in the Assembly of the Envelope section.

Consistent with its central role in virus budding, M is often inactivated in persistent paramyxovirus infections where budding fails to occur. For example, in subacute sclerosing panencephalitis (SSPE)—a rare, progressive, and invariably fatal persistent measles virus infection of the brain—the M protein is either absent for various reasons⁴⁷ or, when present, is not associated with budding structures *in vivo* and is unable to bind to viral nucleocapsids *in vitro*.¹⁶² Although a genetically engineered recombinant measles virus that lacks a matrix

protein has been obtained,⁴⁵ it produces approximately 4 logs lower titer of released infectious particles than wild-type virus and remains mostly cell associated. Therefore, it is reasonable to conclude that the M protein does play a very important function in virus assembly. Moreover, in model systems of persistent Sendai virus infection in culture, the normally lytic infection is converted to a persistent one using defective interfering particles. This change correlates mainly with M protein instability and an absence of budding structures.³⁴¹

The M protein of several paramyxoviruses is phosphorylated. For Sendai virus, a large proportion of the M protein is phosphorylated, whereas the M protein found in virions is not phosphorylated.²¹² However, a Sendai virus could be rescued from an infectious complementary DNA (cDNA) in which the single phosphorylation site in Sendai virus M protein had been eliminated.³⁴⁸ This M protein phosphorylation-minus mutant did not show an altered phenotype from wild-type virus in either cultured cells or mice.

Envelope Glycoproteins

All *Paramyxoviridae* possess two integral membrane proteins, and some rubulaviruses and all pneumoviruses encode a third integral membrane protein (Fig. 33.11). One glycoprotein (HN, H, or G) is involved in cell attachment and the other glycoprotein (F) in mediating pH-independent fusion of the viral envelope with the plasma membrane of the host cell. The *Rubulavirus* and *Pneumovirus* third integral membrane protein is referred to as SH; for PIV5, this 44 amino acid integral membrane protein is thought to block virus-induced apoptosis. The assignment of specific biological activities of F and HN was originally made on the basis of purification and reconstitution studies, mainly for the Sendai virus and PIV5 proteins.^{353,354} The attachment proteins (HN, H, or G) are all

type II integral membrane proteins, and bioinformatics and structural predictions indicate that the proteins will all exhibit a related propeller-like fold despite having different receptors and the presence or absence of NA activity.

For the respiroviruses and rubulaviruses, the attachment glycoprotein binds to cellular sialic acid-containing receptors, and these can be glycoproteins or glycolipids. The binding is probably of fairly low affinity but of sufficiently high avidity that these viruses agglutinate erythrocytes (hemagglutination). The attachment proteins of respiroviruses and rubulaviruses also have NA activity (receptor-destroying activity), and the proteins have been designated hemagglutinin-neuraminidase (HN). However, a possible role of a specific protein-protein involvement in infection of host cells has not been ruled out.

The restricted host range of measles virus for primate cells and the lack of NA or esterase activity make it unlikely that sialic acid is the primary receptor for measles virus. Nonetheless, the *Morbillivirus* attachment protein (H) can cause agglutination of primate erythrocytes, most likely owing to receptor binding: the designation of measles and CDV glycoprotein as H is thus a misnomer. In 1993, human CD46 was identified as a cellular receptor for Edmonston and Halle strains of measles virus.^{91,282} Edmonston and Vero cell-isolated strains of measles virus are capable of infecting any CD46⁺ primate cell. However, viruses isolated from B- and T-cell lines do not grow in CD46⁺ cells. A second receptor was identified—human CD150 (SLAM), a membrane glycoprotein involved in lymphocyte activation.^{404,442} It is now thought that CD150 is the principle receptor for unadapted isolates of lymphotropic measles virus.²⁹¹

Very recently, a third receptor for measles virus has been identified, known as poliovirus receptor-like (PVRL4; Nectin 4) or adherens junction protein nectin 4. It is proposed that this new receptor is the epithelial receptor for measles virus that

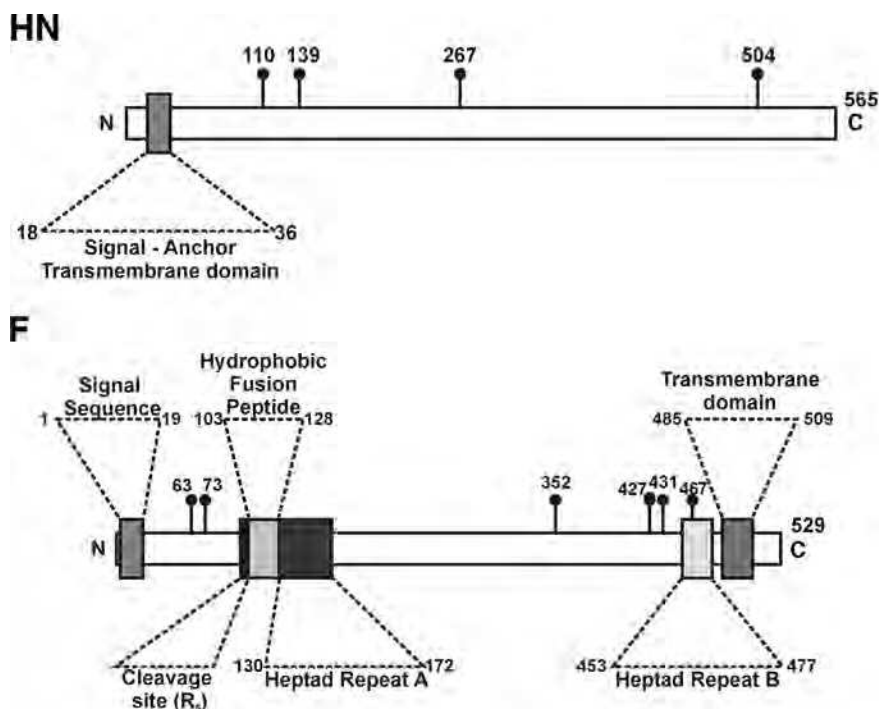

FIGURE 33.11. Schematic diagram showing the orientation and domains of paramyxovirus integral membrane proteins. A: Hemagglutinin-neuraminidase (HN) attachment protein (based on the predicted sequence of the parainfluenza virus type 5 [PIV5] HN gene.¹⁵⁹ The signal anchor transmembrane domain and the sites used for addition of N-linked carbohydrate (*lollipop*s)²⁸⁵ are indicated. **B:** Fusion protein (based on the predicted sequence of the PIV5 F gene). The position of the signal sequence, the transmembrane domain, the cleavage site, the hydrophobic fusion peptide, and the heptad repeats A and B are indicated. The sites used for addition of N-linked carbohydrate (*lollipop*s)⁸ are indicated. R₅ indicates the five arginine residues site for cleavage activation.

is used to transfer virus from the basolateral surface of epithelial cells to the luminal side of the airway.^{270,288}

The receptor for Hendra virus and Nipah virus G glycoprotein has been shown to be ephrin-B2 or ephrin-B3. In one approach, direct binding of Nipah G to receptor was obtained and the identity of the receptor determined by protein sequencing and bioinformatics.²⁸⁴ In another approach, microarray analysis was used to identify mRNAs that were expressed in henipavirus-susceptible cells and not in cells refractory to henipavirus infection.²⁰ Ephrin-B2 and -B3 are members of a family of cell surface glycoprotein ligands that bind to ephrin (Eph) receptors—a large family of tyrosine kinases. The identification of ephrin-B2/B3 as the cellular receptor for both Hendra virus and Nipah viruses and the widespread occurrence of ephrin-B2/3 in vertebrates, particularly in arterial endothelial cells and in neurons, provides an explanation for the wide host range of henipaviruses and their systemic infection.⁹⁸

The *Pneumovirus* RSV does not cause detectable hemagglutination, and the cellular receptor for RSV is not completely understood but involves interactions with heparan sulfate—a glycosaminoglycan that is part of the extracellular matrix. Interestingly, the G protein of RSV and human metapneumovirus (HMPV) can be deleted from the viral genome,¹⁸⁹ and Sendai virus-like particles devoid of HN can infect cells via the asialoglycoprotein receptor.²²⁴ Both of these cases suggest that some paramyxovirus F proteins may have a binding activity. After attachment of a *Paramyxoviridae* particle to the host cell receptor, the viral envelope fuses with the host cell plasma membrane, and the major viral protein involved in this process is the F glycoprotein.

Paramyxovirus Attachment Protein

The *Respirovirus* and *Rubulavirus* surface glycoprotein HN is a multifunctional protein and the major antigenic determinant of the paramyxoviruses. HN has three activities: (a) receptor binding to sialic acid; (b) cleavage of sialic acid from complex carbohydrate chains (NA activity); and (c) fusion promotion—that is, co-expression of HN and F is required for cell–cell fusion (see later discussion). By analogy to the role of influenza virus NA, it seems likely that the role of this NA activity is to prevent self-aggregation of viral particles during budding at the plasma membrane. These dual activities of HN can be modulated by pH.²⁵⁸ Whereas the pH of the extracellular environment is optimal for hemagglutination, paramyxovirus NAs have an acidic pH optima (pH 4.8–5.5), suggesting that NA acts in the acidic *trans*-Golgi network to remove sialic acid from the HN carbohydrate chains and from the F protein carbohydrate chains.

The HN polypeptide chain ranges from 565 to 582 residues. For some strains of NDV, HN is synthesized as a biologically inactive precursor (HN₀), and 44 residues from the C-terminus are removed to activate the molecule.^{278,279} HN is a type II integral membrane protein that spans the membrane once and contains an N-terminal cytoplasmic tail, a single N-terminal transmembrane (TM) domain, a membrane-proximal stalk domain, and a large C-terminal globular head domain.¹⁵⁹ The globular head domain contains the receptor-binding and enzymatic activity.^{301,353,410} HN is glycosylated and contains from four to six potential sites for the addition of N-linked carbohydrate chains. For PIV5 and NDV HN, it is known that four sites are used.^{253,285} HN is noncovalently associated to form a dimer of dimers, based on biochemical, cross-linking,

electron microscopy, and structural studies that, depending on the paramyxovirus, can be composed of two disulfide-linked dimers.^{72,148,218,252,285,286,409,450,451} The covalent linkage occurs through a cysteine residue at the C-terminal end of the stalk domain, just prior to the beginning of the head domain. The stalk domain appears to play an essential role in the formation of the tetramer,⁴⁵¹ and head domains when expressed without the stalk are often monomeric.^{72,218,451}

The structure of the enzymatically active head domain of HN is similar to other NAs or sialidases, such as influenza NA,¹⁰³ with the globular head composed of identical subunits. Each NA domain exhibits the six-blade propeller fold typical of other NA/sialidase structures from viral, protozoan, or bacterial origin.^{41,216,405} Atomic structures of soluble head domains of NDV, HPIV3, PIV5 (liganded and bound to a receptor/substrate sialyllactose), measles virus H (unliganded and bound to its receptor CD150/SLAM), and Hendra and Nipah virus G (unliganded and bound to its receptor ephrin-B2 or ephrin-B3) have been obtained,^{30,31,60,72,148,149,218,441,451,453} and it shows the typical sialidase fold consisting of six antiparallel β -strands organized as a super barrel with a centrally located active site (Fig. 33.12). The seven highly conserved active site residues found in NA and sialidases are found in the paramyxovirus HN structures. However, these key active site residues are mutated in the measles H and Nipah/Hendra G proteins, rendering these proteins enzymatically dead. Superimposition of the NDV, HPIV3, and PIV5 HN monomer structures indicates a high degree of conservation on one face of the molecule, with the other face containing more variability and additional protein loops.⁴⁵¹

It has long been debated whether the hemagglutinin and NA activities of HN involve one or two separate sialic acid binding sites.^{72,329,453} The disparate theories of one site with dual function or of two distinct sites that are intimately related are both consistent with the observation that sialic acid–derived NA inhibitors interfere with receptor binding.^{177,275,355} A single site can provide both hemagglutinin and NA activities by binding sialic acid tightly and hydrolyzing the molecules slowly.³⁵⁵ For NDV HN, two sialic acid sites have been observed in the x-ray structures: one is the active site, and a second site is located at the dimer interface.⁴⁵³ Strong biological evidence supports the notion of a second sialic acid binding site in NDV.^{29,323} Mutagenesis of a key residue involved in the dimer interface sialic acid binding site abolishes sialic acid binding to the second site.²⁹ However, virus containing this key residue mutation is only marginally affected in growth properties.²⁹ For HPIV3, the second sialic acid binding site is blocked by a carbohydrate chain that prevents its function,²⁶¹ although mutagenesis to ablate the carbohydrate chain allows the HPIV3 second site to bind sialic acid. The growth curve of HPIV3 with or without the carbohydrate chain that shields the second sialic acid binding site is very similar, suggesting no major biological importance.

For PIV5 HN, not only was a second sialic acid binding site not observed, the molecule could not form the second sialic acid binding site between two monomers owing to changes in sequence and conformation.^{218,451} Thus, the biological importance of the second sialic acid binding sites in NDV HN and the one created in HPIV3 by removal of the carbohydrate addition site are a conundrum.^{261,322,325}

From the structural studies of NDV HN, it was also suggested that the NA domain could form two distinct dimeric

FIGURE 33.14. Structure of the Newcastle disease virus (NDV) hemagglutinin-neuraminidase (HN) (Stain Australian–Victoria) ectodomain. A:

Two dimers of the NDV HN neuroaminidase (NA) domains flank the four-helix bundle in the stalk. The four NA domains are labeled NA1 through NA4. The active sites are marked by three residues shown as *blue* CPK spheres (E400, R415, and Y525) and labeled accordingly. The secondary sialic acid binding sites located at the NA domain dimer interfaces are marked by residues shown as *orange* CPK spheres and labeled (second sites). The N-termini of the four NA domains, residues 123 and 125, are labeled and indicated by their α atoms shown in CPK format colored by chain. The connections of the N-terminal region of the stalk to the HN transmembrane domains and viral membrane are indicated.

B: End-on view of the packing of the HN stalk tetramer between two NA domain dimers rotated through 90 degrees as indicated by the *curved arrow*. Although no electron density was observed to connect the HN stalk helices with the individual NA domains, the *dotted lines* indicate possible linkages between these domains, with NA1/NA2 and NA3/NA4 forming covalently linked dimers through C123. The four-stalk helices are indicated as h1 through h4. (Adapted from Yuan P, Swanson KA, Leser GP, et al. Structure of the Newcastle disease virus hemagglutinin-neuraminidase [HN] ectodomain reveals a four-helix bundle stalk. *Proc Natl Acad Sci U S A* 2011;108:14920–14925.)

to each other and in the crystal lattice, allowing neighboring dimers and tetramers to associate in infinitely long oligomers. The dimer places the two HN active sites at nearly 90 degrees to each other. The calculated buried surface area for each monomer in the PIV5 HN dimer is 1,818 Å². In contrast to the dimer interaction, the dimer-of-dimers interface is much smaller, involving only 10 residues and burying only 657 Å². The small surface of interaction suggests that the arrangement is not very strong and that the dimers may dissociate.

Recently, the atomic structure of the NDV head domain with a tetrameric stalk has been obtained⁴⁵⁰ (Fig. 33.14). The stalk forms a four-helix bundle, and on either side are dimers of head domains. One head domain of each dimer makes extensive interactions with the stalk. This structure, as compared with the head-only tetramer,⁴⁵¹ suggests plasticity in the stalk/head-connecting region.

The structure of the *Pneumovirus* attachment protein (G) is very different from the attachment protein of the *Paramyxovirinae*. The RSV G protein has neither hemagglutinating nor NA activity. The nucleotide sequence of the RSV G gene predicts

that the protein is of 289 to 299 amino acids (M_r)^{32,587} and is a type II integral membrane protein with a single N-terminal hydrophobic signal/anchor domain.^{352,435} The G protein is found in virus-infected cells in both membrane-bound and proteolytically cleaved soluble forms. The distinguishing feature of the RSV G protein is the extent of its carbohydrate modification. On SDS-PAGE, the protein migrates with an apparent M_r of approximately 84,000 to 90,000, and the dramatic increase in molecular weight over that predicted for the polypeptide chain is because 8 to 12 kDa is owing to addition of N-linked carbohydrate (four potential addition sites) and 40 to 50 kDa is owing to the addition of O-linked glycosylation (77 potential acceptor serine or threonine residues; 30% of total residues) (61 and references therein). Quite remarkably, it appears that the RSV G protein is not essential for virus assembly or growth in tissue culture or animals, although it does confer a growth advantage. A virus that had been extensively passaged in cells was found to contain a spontaneous deletion of the G and SH genes,¹⁸⁹ yet the virus replicated in Vero cells. In addition, the G gene has been deleted from recombinant virus recovered from

an infectious cDNA clone (see Chapter 38). These findings suggest that RSV has an alternate mechanism for attachment to cells that does not involve G protein, and evidence has been obtained that RSV lacking G protein can bind to heparan sulfate and possibly other molecules.^{111,140,406} Similar observations have been made for HMPV.⁵⁷

Paramyxovirus Fusion Protein

The paramyxovirus fusion (F) proteins mediate viral penetration by fusion between the virion envelope and the host cell plasma membrane, and this fusion event occurs at neutral pH for all family members except a few isolates of HMPV, where low pH appears to have some role in fusion activation.^{249,362} The consequence of the fusion reaction is that the nucleocapsid is delivered to the cytoplasm. Later in infection, the F proteins expressed at the plasma membrane of infected cells can mediate fusion with neighboring cells to form syncytia (giant cell formation), which is a cytopathic effect that can lead to tissue necrosis *in vivo* and might also be a mechanism of virus spread.

The F proteins are homotrimers^{58,346,444,445} that are synthesized as inactive precursors (F₀). To be biologically active, they have to be cleaved by a host cell protease at the cleavage activation site. Cleavage releases the new N-terminus of F₁, thus forming the biologically active protein consisting of the disulfide-linked chains F₁ and F₂.^{167,354} The paramyxovirus F genes encode 540 to 580 residues (see Fig. 33.11). The F proteins are type I integral membrane proteins that span the membrane once and contain at their N-terminus a cleavable signal sequence that targets the nascent polypeptide chain syn-

thesis to the membrane of the endoplasmic reticulum. At their C-termini, a hydrophobic stop-transfer domain (TM domain) anchors the protein in the membrane, leaving a short cytoplasmic tail (~20–40 residues). Sequences adjacent to the fusion peptide and the TM anchor domain typically reveal a 4–3 (heptad) pattern of hydrophobic repeats and are designated HRA and HRB, respectively. Approximately 250 residues separate HRA and HRB (Fig. 33.15A).

Evidence has been presented that there is a second polytopic form of the NDV F protein that is 10% to 50% of the total F protein.²⁵⁴ The proposed second polytopic form of F has not been found for other paramyxovirus F proteins, and it is unclear why NDV F protein would be different from other F proteins. Because the second form of NDV F is only partially membrane translocated, it would have a very different protein fold from prefusion F (see Fig. 33.15), and it is unclear why NDV would uniquely require this form of F for the viral replication cycle.

The F protein is thought to drive membrane fusion by coupling irreversible protein refolding to membrane juxtaposition, initially folding into a metastable form that subsequently undergoes discrete/stepwise conformational changes to a lower energy state.^{183,211} The F protein found on virions is considered to be in a prefusion form; after membrane fusion has occurred, the F protein is considered to be in a postfusion form. Cleavage of F₀ primes the protein for membrane fusion. The varying nature of the residues found at the cleavage site, the enzymes involved in cleavage, and the role of cleavage in pathogenesis will be discussed later.

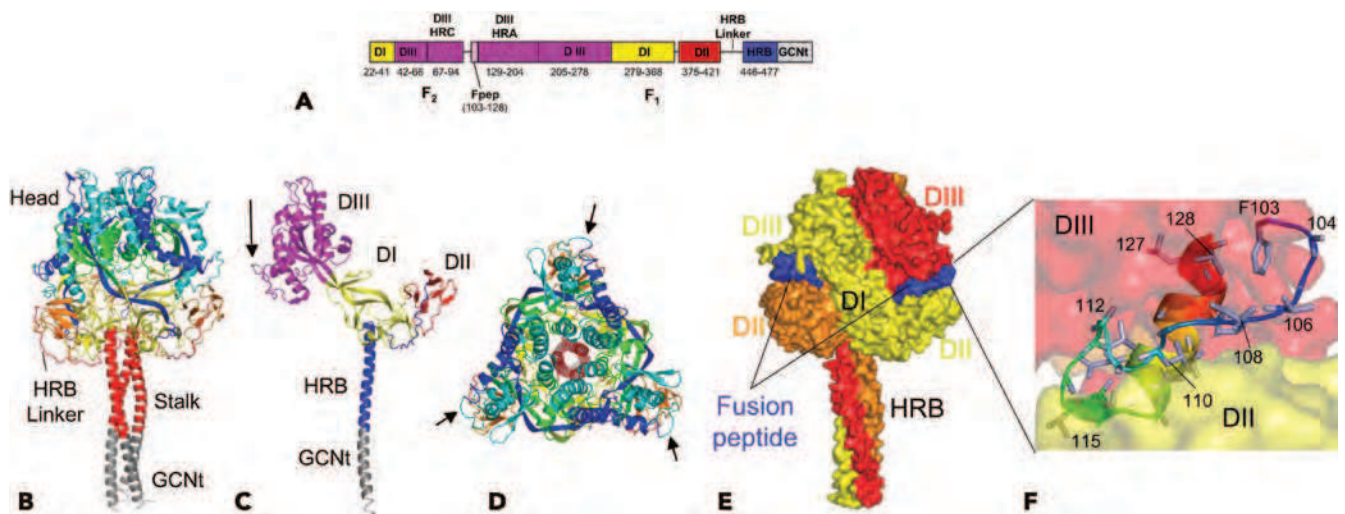

FIGURE 33.15. The fusion (F) protein prefusion structure. **A:** Schematic diagram of the F-GCNt domains. Important domains are colored and their corresponding residue ranges indicated. **B:** Ribbon diagram of the F trimer, with each chain colored by residue number in a gradient from blue (N-terminus) to red (C-terminus). The head and stalk regions are indicated. HRB linker residues 429 through 432 could not be modeled in one subunit and had high temperature factors in the other two. **C:** Ribbon diagram of one subunit of the F trimer colored by domain. The domains are labeled, and the colors correspond to those used in **A**. The cleavage/activation site is indicated with an arrow. **D:** Top view of the trimer colored as in **A**. Cleavage/activation sites are indicated by arrows. **E:** Surface representation of the F trimer colored by subunit. The fusion peptide exposed surface is colored blue. **F:** Close-up view of the fusion peptide (residues 103–128). The peptide is folded back on itself with a small hydrophobic core and contains a mixture of extended chain, one β -strand and a C-terminal α -helix. The fusion peptide is sandwiched between two subunits of the trimer, between DII and DIII domains. (Adapted from Yin HS, Wen X, Paterson RG, et al. Structure of the parainfluenza virus 5 F protein in its metastable, prefusion conformation. *Nature* 2006;439:38–44.)

Comparison of the amino acid sequences of paramyxovirus F proteins (reviewed in 267) does not show overall major regions of sequence identity, with the exception of the fusion peptide, which has a conserved sequence (up to 90% identity). However, the overall placement of cysteine, glycine, and proline residues suggests a similar structure for all F proteins. The *Respirovirus* and *Rubulavirus* F2 and F1 subunits are glycosylated, and there are a total of 3 to 6 potential sites for the addition of N-linked carbohydrate. For PIV5 F protein, it is known that all four potential sites for addition of N-linked carbohydrate are used.⁸ The measles virus F protein contains three sites in the F2 subunit for N-linked carbohydrate addition, and all three sites are used; there are no sites in F1 for N-linked carbohydrate addition.¹

CLASS I VIRAL FUSION PROTEINS

The paramyxovirus F proteins belong to the class I viral fusion protein type, of which the longest standing member is the influenza virus hemagglutinin. Class I also includes the fusion proteins from retroviruses including human immunodeficiency virus type 1 (HIV-1; Env/gp160), coronaviruses (S), and Ebola virus (G).^{67,96,97,183,213} Models for class I viral fusion protein-mediated membrane merger have been developed, until recently, primarily from the structural studies of hemagglutinin.³⁷³ The general mechanism for class I viral fusion proteins posits the folding of the uncleaved protein to a metastable state, which can be activated to undergo large conformational changes to a more stable fusogenic or postfusion state. The attainment of the prefusion conformation, its regulation, and relative free energy as compared to the postfusion form are all key to the process by which class I viral fusion proteins function.

CLASS I VIRAL FUSION PROTEINS AND THE HELICAL HAIRPIN (CORE TRIMER)

Biophysical data has indicated that HRA and HRB form a complex, and crystallographic studies have shown that HRA and HRB form a helical hairpin or six-helix bundle (6HB) structure (core trimer) that is related to that observed for the low-pH induced proteolytic fragment of hemagglutinin (TBHA2). For example, the core trimers of PIV5 and human RSV F,^{9,187,456} human immunodeficiency virus (HIV) gp41,^{42,55,396,432} Moloney murine leukemia virus envelope protein,¹⁰⁷ Ebola GP2,^{235,433} and human T-cell leukemia virus type 1 (HTLV-1)²⁰² fusion proteins all share this similarity in structure (Fig. 33.16A). Although the structural details vary, all reveal a trimeric, coiled-coil beginning near the C-terminal end of the hydrophobic fusion peptide. The C-terminal segment abutting the TM domain is also often helical and packs in an antiparallel direction along the outside of the N-terminal coiled-coil, placing the fusion peptides and TM anchors at the same end of a rod-like structure (for PIV5 6HB, see Fig. 33.16A). These 6HBs typically represent a relatively small fraction of the intact fusion protein, yet their structures are generally highly thermostable, with melting temperatures near 100°C. Intermediates along the pathway of membrane fusion can be trapped by the addition of peptides derived from either the N-terminal (HRA) or C-terminal (HRB) heptad repeat regions for many class I fusion proteins,^{97,100,106,344,449} indicating that the intact protein undergoes conformational changes that expose both HR regions prior to refolding to the final 6HB. The intermediates are thought to represent partially refolded forms of the fusion protein, with a hydrophobic fusion peptide anchored in the target cell membrane and the TM domains

FIGURE 33.16. The F protein postfusion structure. **A:** The complete parainfluenza virus type 5 (PIV5) F1 core trimer is shown with the N1 helix colored *gray* and the C1 peptide colored *blue* except for the extended-chain N-terminal residues of C1 that are colored *red*. **B:** Ribbon diagram of the HPIV3 solF0 trimer. The three chains are colored similarly from *blue* (N-terminus) to *red* (C-terminus). Residues 95 through 135 are disordered in all chains. Residue 94 is labeled in one chain, and residues 136 through 140 at the base of the stalk are ordered in one chain owing to crystal packing interactions. **C:** Surface representation of the solF0 trimer. Each chain is a different color, and domains I through III and HRB for one chain (*yellow*) are indicated by the DI, DII, DIII, and HRB labels. One radial channel is readily apparent below domain I and II of the yellow chain and above domain III of the red chain. **D:** Ribbon diagram of the solF0 protein monomer colored by domain. The direct distance within one monomer between residue 94 at the end of HRC and residue 142 at the base of the stalk region is 122 Å. **E:** Ribbon diagram of the monomer rotated by 90 degrees, indicating the width and height of the solF0 monomer. An *arrow* at the C-terminus of the HRB segment points toward the likely position of the transmembrane anchor domain that would be present in the full length protein. (Adapted from Yin H-S, Paterson RG, Wen X, et al. Structure of the uncleaved ectodomain of the paramyxovirus [HPIV3] fusion protein. *Proc Natl Acad Sci U S A* 2005;102:9288–9293.)

anchored to the viral membrane. The formation of the 6HB is tightly linked to the merger of lipid bilayers and is thought likely to couple the free energy released on protein refolding to membrane fusion.^{257,344}

ATOMIC STRUCTURES OF THE PARAMYXOVIRUS F PROTEIN

Structure of the Prefusion F Protein. The atomic structure of the PIV5 F protein in its uncleaved metastable prefusion form has been determined.⁴⁴⁵ To solve the atomic structure, the secreted F protein was stabilized by the addition of a soluble trimeric TM domain (GCNt) that supplants the hydrophobic TM domain. The F trimer has a large globular head attached to a three-helix coiled-coil stalk formed by HRB (see Fig. 33.15B–E) orienting the head away from the viral membrane. The F head contains three domains (DI–DIII) per subunit that extend around the trimer axis, making extensive intersubunit contacts. A large cavity is present at the base of the head, with the bottom and sides formed by DI and DII. DIII (residues 42–278) covers the top of the cavity, HRA, and the fusion peptide (see Fig. 33.15B–D). At the C-terminus of DII, an extended linker to HRB wraps around the outside of the trimer and into the center of the base of the head where the stalk begins. The structure has three lateral vertices projecting from the trimer axis, exposing the cleavage/activation sites adjacent to the fusion peptides (see Fig. 33.15C,D). Helices line the central threefold axis at the top and bottom of the trimer. In DIII, two sets of six helices form rings sealing the top of the head, whereas the HRB three-helix bundle seals the bottom (see Fig. 33.15D).

In the prefusion PIV5 F structure, the hydrophobic fusion peptide (residues 103–128) is wedged between two subunits of the trimer (see Fig. 33.15E). The N-terminal end of the fusion peptide is exposed at the F surface and then proceeds inward, becoming more buried from solvent. The fusion peptide adopts a partly extended, partly β -sheet, and partly α -helical conformation and is sandwiched between DIII of its own

subunit and DII of another. Residues 107 through 117 pack against the hydrophobic edge of the neighboring DII domain. The fusion peptide folds back on itself, forming a small hydrophobic core between its N-terminal and C-terminal ends, making less extensive contacts with DIII (see Fig. 33.15E,F). Proteolytic cleavage of F0 might allow the N-terminus of the fusion peptide to make additional contacts with DII and to affect intersubunit interactions.

Structure of the Postfusion Form of the F Protein. The atomic structure of intact F protein in its postfusion form has been determined for HPIV3, NDV, and RSV.^{255,388,389,444} The structure of the HPIV3 F protein was solved by molecular replacement, using as a model the structure of a proteolytic fragment of NDV F,⁵⁸ now known to be in its postfusion form.

HPIV3 F forms a trimer, with distinct head, neck, and stalk regions (Fig. 33.17A–D). The only part of the structure lacking electron density is the fusion peptide and cleavage site; however, the residues would be draped flexibly on the exterior of the stalk region. Given that the uncleaved F ectodomain was secreted from cells by removal of the TM domain, it was initially unexpected that the structure contained a 6HB (see Fig. 33.17A–D) that represents the postfusion conformation of the protein. It had been widely anticipated that cleavage of F at the cleavage site was a requirement for conversion to the postfusion form. Nonetheless, many lines of evidence suggested that the observed HPIV3 conformation represented the postfusion form, although the polypeptide chains were intact in the crystal and the fusion peptide was not located at the appropriate end of the 6HB.

The observation that the soluble, secreted HPIV3, NDV F, and RSV F proteins were in the postfusion conformation was unexpected, and there are at least two possible explanations for this finding. First, the TM anchor (and potentially the cytoplasmic tail)⁴²⁸ could be an important determinant of the stability of the prefusion conformation, providing a

FIGURE 33.17. Structural changes between the pre- and postfusion F protein conformations.

A: Ribbon diagram of the parainfluenza virus type 5 (PIV5) F-GCNt trimer. DI is colored yellow, DII is colored red, DIII is colored magenta, HRB is colored blue, and GCNt is colored gray. **B:** Ribbon diagram of the human parainfluenza virus type 3 (HPIV3) (postfusion) trimer, colored as in **A**. **C:** Ribbon diagram of a single subunit of the PIV5 F-GCNt trimer, colored as in **A**, except for HRA residues, which are colored green. **D:** Ribbon diagram of a single subunit of the HPIV3 F trimer, colored as in **C**. significant fraction of the energy barrier that traps the protein in a metastable state. In this case, the secreted protein may fold to the prefusion form transiently but then refold to the postfusion form. A second possible explanation for the structural results is that the TM domain is important for the protein to attain the prefusion metastable state and that in the absence of this region, the soluble F protein folds directly to the final, most stable postfusion conformation. In either case, it appears that the amino acids comprising the intact F protein ectodomain are not sufficient for the protein to fold to and maintain a metastable conformation. Hence, to trap a soluble form of the F protein in its metastable form, the F protein was stabilized by the addition of a soluble trimeric TM domain (GCNt) that supplants the hydrophobic TM domain.

COMPARISON OF THE PREFUSION AND POSTFUSION F STRUCTURES

The PIV5 prefusion F and HPIV3 postfusion F structures are in strikingly different conformations (see Fig. 33.17), consistent with a transition from pre- to postfusion forms. None of the intersubunit contacts are conserved in the pre- and postfusion forms. The two F structures are related by flipping the stalk and TM domains relative to the F head. Substantial compacting of the head is observed in HPIV3 postfusion F compared to PIV5 prefusion F. DI domains pivot slightly inward, shearing intersubunit contacts, and DII domains swing across, contacting neighboring subunits. Individual DI and DII domains in the two structures remain similar. Potentially related forms of the F protein have been observed in electron micrographs of RSV F.^{44,130,342,343}

DIII undergoes major refolding between the two structures, projecting a new coiled coil (HRA) upward and away from DI, the prefusion stalk, and the viral membrane. The fusion peptide, located at the top of the HRA coiled coil, moves

approximately 115 Å from its initial position between subunits in the prefusion conformation, allowing DII domains to reposition. None of the postfusion HRA intersubunit coiled-coil contacts are observed in F-GCNt. Instead, they are replaced by two sets of six-helix rings at the DIII interfaces (see Fig. 33.15D). For the HRA coiled coil to form, DIII must rotate and collapse inward, further compacting the head.

The F protein refolding also requires the opening and translocation of the HRB stalk (see Fig. 33.17). In the prefusion form, HRB is located at the base of the head region. During the conversion to the postfusion conformation, HRB segments must separate and swing around the base of the head to pack against the HRA coiled coil. In the prefusion conformation, HRA is broken up into four helices, two β -strands, and five loop, kink, or turn segments. Thus, the conformational changes in HRA involve the refolding of 11 distinct segments into a single, extended α -helical conformation (Fig. 33.18).

THE MECHANISM OF PARAMYXOVIRUS-MEDIATED MEMBRANE FUSION

The prefusion and postfusion F structures suggest how discrete refolding intermediates are coupled to the activation and progression of F-mediated membrane fusion. Whereas proteolytic cleavage of the paramyxovirus F protein is required for membrane fusion activity, it is not required for the formation of the postfusion conformation. A model for membrane fusion is as follows. In the first step, the HRB helices melt (open-stalk form, Fig. 33.19), breaking interactions at the base of the head but leaving HRA in the prefusion conformation. This intermediate is consistent with effects of mutations of PIV5 residues 443, 447, and 449 as well as peptide inhibition data.^{305,344,345} HRA-derived peptides, which likely bind to the endogenous HRB segment, inhibit an early intermediate along the fusion

FIGURE 33.18. F protein refolding: the role of DIII in HRA folding and transformation. **A:** HRA refolds from 11 distinct segments (h1, h2, b1, b2, h3, h4, and the intervening residues) in the prefusion conformation into a single, nearly 120 Å long helix in the postfusion form. **B:** Secondary structure diagram for DIII in the prefusion (parainfluenza virus type 5) conformation. The “DIII core” includes three antiparallel strands, HRC, a helical bundle (HB), and h4 of HRA. HRA segments are colored as in **A**, and the cleavage site (//) and fusion peptide are indicated. The DIII core sheet is extended by the b1 and b2 strands from HRA. **C:** Secondary structure diagram for DIII in the postfusion (human parainfluenza virus type 3) conformation. The DIII core sheet is extended by one strand from HRB linker from a neighboring subunit (dark violet). (Adapted from Yin HS, Wen X, Paterson RG, et al. Structure of the parainfluenza virus 5 F protein in its metastable, prefusion conformation. *Nature* 2006;439:38–44.)

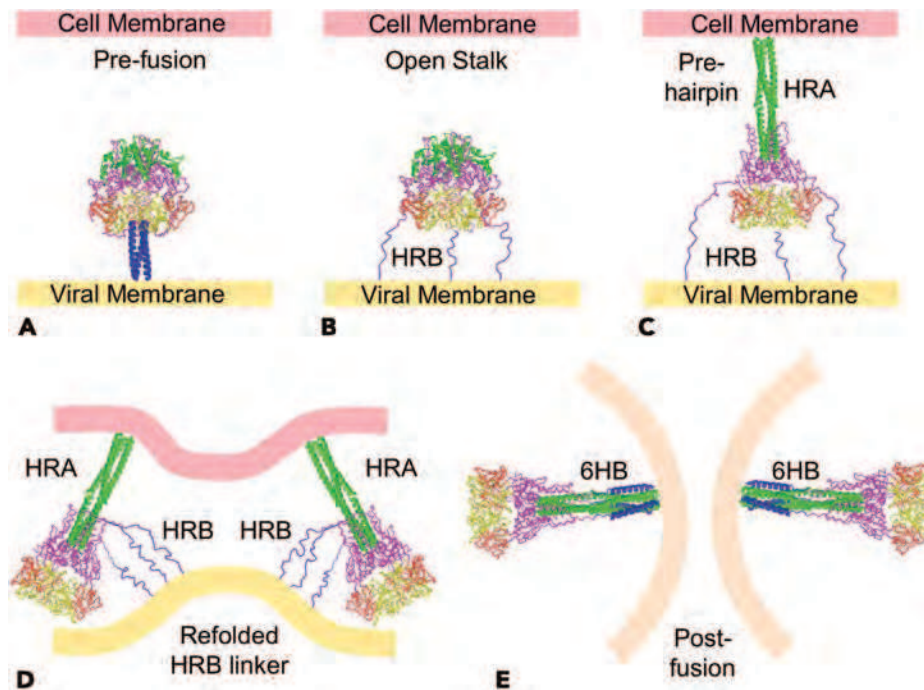

FIGURE 33.19. A model for F-mediated membrane fusion. **A:** Structure of the prefusion conformation. HRB is colored *blue*, HRA is colored *green*, and domains I, II, and III are colored *yellow*, *red*, and *magenta*, respectively. **B:** An open-stalk conformation, in which the HRB stalk melts and separates from the prefusion head region. HRB is shown as three extended chains because the individual segments are unlikely to be helical. This conformation is consistent with a low-temperature intermediate that is inhibited by HRA peptides but not HRB peptides. Mutations of the switch peptide residues 443, 447, and 449 would influence the formation of this intermediate by affecting stabilizing interactions between the prefusion stalk and head domains. **C:** A pre-hairpin intermediate can form by refolding of DIII, allowing the formation of the HRA coiled coil and insertion of the fusion peptide into the target cell membrane. This intermediate can be inhibited by peptides derived from both HRA and HRB regions. **D:** Prior to forming the final six-helix bundle, the close approach of viral and cellular membranes may be trapped by folding of the HRB linker onto the newly exposed DIII core, with the formation of two β -strands (see Fig. 33.15D,F). **E:** The formation of the postfusion six-helix bundle is tightly linked to membrane fusion and pore formation, juxtaposing the membrane interacting fusion peptide and transmembrane domains. (Adapted from Yin HS, Wen X, Paterson RG, et al. Structure of the parainfluenza virus 5 F protein in its metastable, prefusion conformation. *Nature* 2006;439:38–44.)

pathway, whereas HRB-derived peptides inhibit a later intermediate by binding the endogenous HRA coiled coil. Opening of the HRB stalk could initiate further changes in F by affecting the packing of DII and the fusion peptide (through the HRB linker) and by affecting the stability of the head intersubunit contacts, which shift during the conformational transition. It seems possible that transient dissociation of the F trimer could occur, analogous to the dimer-to-trimer transition characterized in alpha- and flavivirus fusion proteins (Chapter 3). The open-stalk intermediate is then likely followed by refolding of DIII, the assembly of the HRA coiled coil, and the translocation of the fusion peptide toward the target cell membrane (see Fig. 33.19). This pre-hairpin intermediate has been trapped and co-precipitated with HRB peptides³⁴⁴ and imaged by electron microscopy.¹⁹⁸ Removal of the fusion peptide from the intersubunit interfaces would enable an inward swing of DII and the formation of new contacts with DI of a neighboring subunit, compacting the head. The refolding of DIII HRA would also expose its core β -sheet, and together with the inward movement of DII allow the HRB linker (at the C-terminus of DII) to form parallel β -strands with the DIII core, likely preceding and initiating the final positioning of HRB (see Fig. 33.19). The assembly of the final

6HB completes the conformational change and membrane merger.

HN ACTIVATES THE F PROTEIN FOR MEMBRANE FUSION

The triggering mechanism that regulates the F protein conformational changes such that it occurs at the right place and the right time is not fully understood, although as described later for most paramyxoviruses, there is a requirement for the receptor-binding protein (HN, H, or G) in mediating the fusion reaction.^{215,268} The precise role of the HN, H, or G protein in stimulating the F conformational change remains to be understood; however, the emerging picture indicates a regulated complex biological machine.^{178,222,318}

For all paramyxoviruses, co-expression of F and HN (H or G) is either required for fusion or co-expression of HN (H or G) makes fusion more efficient.^{51,99,173,176,266,349,438,443} Furthermore, the homotypic HN (i.e., of the same virus), not a heterotypic HN, has to be co-expressed in the same cell as the F protein to promote fusion.^{173,176,365} However, expression of the F of PIV5, measles virus, or RSV alone causes some syncytium formation,^{1,173,188,293,302,306} although it is important to note that it is likely that many more cells express the F protein than are found in multinucleated cells.³⁰⁶ Furthermore,

point mutations within NDV F render the protein HN independent for fusion.³⁶⁷ Thus, it seems likely that there are different activation energies for triggering fusion for the different paramyxovirus F proteins. This is highlighted by the observation that PIV5 F-GCnT soluble protein can be converted to the postfusion form by using heat (55°C) as a surrogate for HN activation.⁶⁹

It was hypothesized that a type-specific interaction would occur between the HN and F protein.^{176,211,366} Immunoprecipitation assays show that F and HN co-precipitate, indicating that they can associate^{86,256,381,443}; for HPIV3, F and HN undergo antibody-induced co-capping, indicative of a protein complex formation.⁴⁴³ A great deal of effort has been spent to map the regions of F and HN that interact. One of the difficulties in the work in studying HN is that mutations often affect more than one of the three known biological activities of hemadsorption, NA activity, and fusion promotion. Mutations have been identified in the HN globular domain,^{84,260} the HN stalk,^{23,86,256,295,324,366,382,397,452} and TM anchor^{28,252} that decrease or abolish fusogenic activity with no or little effect on receptor recognition. Analysis of the fusion-promoting activity of chimeric HN molecules derived from different paramyxoviruses largely suggests that the stalk domain and, in some cases, parts of the globular head impart F specificity.^{86,397,414} A point mutation was found in the NDV HN globular head that abolishes both its receptor recognition and NA activity, and that also abolishes its ability to interact with F in co-immunoprecipitation assays.⁸⁵ Based on the view that HRB in F mediates an interaction with HN, it was found that a peptide mimicking HRB bound to a fragment of HN (residues 124–152) when the HN fragment was expressed as an artificial fusion protein.¹³⁶ However, other biological data argues against HN residues 124 through 152 as being part of the F-interactive domain in HN.²⁵⁶

No one model for fusion activation has been universally embraced, and data obtained from studying measles virus and Nipah virus fusion suggest different mechanisms of F protein activation.^{222,318} There are two major models for F activation, with the constant factor being that the HN stalk is required for activation. The *clamp* model (or dissociation model) posits that F and HN/H/G associate with each other in the endoplasmic reticulum and reach the cell surface as a complex that holds F in its metastable prefusion state. Once the attachment protein binds to its receptor, the attachment protein undergoes a conformational change that causes release of F, enabling F to be fusion active. A corollary of the clamp model is that when F is expressed in cells from cDNA without HN/H/G expression, it should be in its postfusion form. The *provocateur* (or association model) posits that F and HN/H/G are transported to the cell surface independently, and on the HN/H/G-binding receptor, there is a conformational change in the receptor-binding protein that leads to complex formation with F, most likely through the HN/H/G stalk, hence triggering fusion activation.^{69,178} Although it is no longer thought that there is a conformational change within an HN/H/G monomer, there is accumulating evidence for more than one form of dimer-dimer interaction^{149,283,450,451} and evidence for the association of the NDV HN dimer with its stalk.⁴⁵⁰

CLEAVAGE ACTIVATION

As discussed previously, the precursor F0 molecule is biologically inactive and cleavage of F0 to the disulfide-linked chains

F1 and F2 activates the protein, rendering the molecule fusion active and permitting viral infectivity. It is important to note that F2 and F1 are not separate domains in the atomic structure of F and thus are not individual parts of the protein. Cleavage of F0 is a candidate to be a key determinant for infectivity and pathogenicity; for certain viruses, this appears to be the case. Proteolytic activation of F0 involves the sequential action of two enzymes: the host protease that cleaves at the carboxyl side of an arginine residue and a host carboxypeptidase that removes the basic residues. The *Paramyxoviridae* can be divided into two groups: those that have F proteins with multibasic residues at the cleavage site and those with F proteins that have a single basic residue at the cleavage site (see Table 33.3). Cleavage of F proteins containing multibasic residues at the cleavage site occurs intracellularly during transport of the protein through the *trans*-Golgi network.

Furin is a cellular protease localized to the *trans*-Golgi network, and its sequence specificity for cleavage is R-X-K/R-R. The available evidence suggests that furin, a subtilisin-like endoprotease, is the (or one of the) protease(s) that cleaves most F proteins intracellularly.^{201,294}

Paramyxoviruses that have F proteins with single basic residues in the cleavage site (e.g., Sendai virus) are not usually cleaved when grown in tissue culture, and thus only a single cycle of growth is obtained. However, the F0 precursor that is expressed at the cell surface and incorporated into released virions can be cleavage activated by the addition of exogenous protease,³⁵⁴ leading to multiple rounds of replication. Purification of a protease from the allantoic fluid of embryonated chicken eggs has indicated that the endoprotease responsible for Sendai virus activation is homologous to the blood clotting factor Xa, which is a member of the prothrombin family.^{132,134} A protease with a similar substrate specificity is secreted from Clara cells of the bronchial epithelium in rats and mice, and this enzyme is probably responsible for activating paramyxoviruses in the respiratory tract. For NDV, the nature of the cleavage site correlates with virulence of the virus. Those strains with multibasic residues in the F0 cleavage site are virulent strains and readily disseminate through the host, whereas those strains with F0 molecules having single basic residues are avirulent and tend to be restricted to the respiratory tracts where the necessary secreted protease can be found.²⁷⁸

A variation on the cleavage theme is found with Hendra virus, as its F protein does not contain a multibasic cleavage site, and yet Hendra F is cleaved in expressing cells at the sequence HDLVDGVK↓,⁷¹ but the K residue is not essential for cleavage.²⁶² In the search for the cleavage enzyme, it was found that inhibition of cathepsin L blocks cleavage,²⁹⁶ suggesting that cleavage occurs in the endocytic pathway.^{89,259} Recent evidence suggests that Hendra F protein is expressed at the cell surface in an uncleaved F0 form, internalized, cleaved by cathepsin in the late endosome, and recycled to the cell surface.³²¹

Another variation on the cleavage theme is found for RSV F protein. The RSV F protein contains two consensus sequences for furin cleavage. One is located at the F2-F1 junction and the other in F2, 27 residues N-terminal to the F2-F1 junction.¹³⁰ Cleavage at both sites is required for fusion activity.⁴⁵⁷

Other Envelope Proteins

The rubulaviruses PIV5 and mumps virus both contain a small gene located between F and HN designated SH.^{160,161} The PIV5

SH protein is a 44-residue, type II integral membrane protein that is expressed at the plasma membrane and is packaged in virions. The mumps virus SH protein is a 57-residue integral membrane protein orientated in membranes in the opposite direction from the PIV5 SH protein with a C-terminal cytoplasmic domain.^{102,393} Owing to the variability in sequence among different strains of mumps virus, the *SH* gene sequence has been used as marker to identify mumps isolates.³⁹⁴ PIV5 lacking SH (PIV5ΔSH) grows as well as wild-type in tissue culture cells; however, the virus is attenuated *in vivo*.¹⁵¹ PIV5ΔSH induces apoptosis in L929 and MDCK cells (but not in HeLa cells) through a tumor necrosis factor alpha-mediated extrinsic apoptotic pathway in the PIV5ΔSH-infected cells.^{152,228} The *SH* gene has been found in all strains of mumps virus, although expression of the SH protein does not seem to be required for mumps virus replication in tissue culture,³⁹³ because in the Enders strain of mumps virus, a monocistronic mRNA encoding SH is not found. Mumps SH may have a similar role as PIV5 SH, considering replacement of PIV5 *SH* gene with the mumps *SH* gene behaves like wild-type PIV5.⁴³⁹ It has been proposed that the attenuating phenotype of viruses with deletions in SH (e.g., PIV5-ΔSH) reflects an altered gradient of transcription rather than a loss of critical function.²³⁶

Members of the *Pneumovirinae* encode a small hydrophobic protein, also designated SH protein. However, this does not necessarily mean that there is a commonality in function with the *Rubulavirus* SH protein. The RSV SH protein contains 64 amino acids and is expressed at the plasma membrane of RSV-infected cells as a type II integral membrane protein and is packaged in virions.^{66,252} In RSV-infected cells, four SH-related polypeptide species have been identified: M_r 4,800; M_r 7,500; M_r 13,000 to 15,000; and M_r 21,000 to 30,000. The M_r 4,800 species is thought to result from the initiation of protein synthesis at an internal AUG codon, the M_r 7,500 species is unglycosylated SH, the M_r 13,000 to 15,000 species is SH

containing one high-mannose N-linked carbohydrate chain, and the M_r 21,000 to 30,000 species is generated by the addition of polylactosaminoglycan to the N-linked carbohydrate chain.^{2,292} The *SH* gene was found to be deleted spontaneously from a virus passed extensively *in vitro*,¹⁸⁹ and it has been deleted from recombinant RSV⁴⁰ with only minor alterations in virus growth properties in tissue culture cells or the respiratory tract of mice or chimpanzees. Thus, the role of the SH protein in the RSV life cycle is not understood.

Pneumovirus M2 Gene

The RSV *M2* gene contains two partially overlapping ORFs, designated M2-1 and M2-2, which give rise to two proteins M2-1 (194 amino acids) and M2-2 (90 amino acids), respectively.⁶⁴ The mechanism for translating the M2-2 ORF is not clear but may involve a ribosomal stop-restart mechanism analogous to that used for synthesis of the influenza B virus BM2 protein¹⁷⁴ (see Chapter 40). The M2-1 protein is an essential transcriptional elongation factor,^{62,109} and in its absence, the polymerase does not transcribe beyond the *NS1* and *NS2* genes.¹⁰⁹ The *M2-1* gene also increases RNAP processivity across the gene junctions, attenuating transcriptional termination.^{109,142,143} The *M2-2* gene is not essential for RSV growth, as it can be deleted from a recombinant RSV.^{14,185} However, the ΔM2-2 virus grows slowly in tissue culture, and there is an increase in transcription and decrease in RNA replication,^{14,185} suggesting that M2-2 protein is involved in regulating transcription and RNA replication. The *M2* gene products of human metapneumoviruses also play a role in controlling viral RNA synthesis, as recombinant HMPV with deletions in the *M2-2* gene showed elevated levels of viral mRNAs.³⁸

Pneumovirus NS1 and NS2 Genes

RSV NS1 (139 amino acids) and NS2 (124 amino acids) are considered to be nonstructural proteins, although the difficulty

in purifying virions from contaminating infected cell debris for this poorly growing virus makes this assignment provisional. Neither protein is thought to be essential for virus growth in cultured cells or in chimpanzees, as the genes can be deleted from a recombinant RSV, although growth *in vitro* and *in vivo* is reduced substantially.^{39,407,437} In a minireplicon system, when NS1 was expressed, it was inhibitory to both transcription and replication,⁶ and expression of NS2 at high levels had a small inhibitory effect on transcription and replication.⁴⁰⁷ Thus, the role of these accessory proteins in controlling RNA synthesis remains to be fully understood. In addition, however,

the human RSV and bovine RSV NS1 and NS2 gene products have been shown to be important viral suppressors of type I IFN induction^{24,377} as described later.

STAGES OF REPLICATION

General Aspects

As far as is known, all aspects of the replication of *Paramyxoviridae* take place in the cytoplasm. An overview of the life cycle of the virus is shown schematically in Figure 33.20, and a

FIGURE 33.20. Schematic representation of the paramyxovirus life cycle. (Refer to the text for details of the viral life cycle.)

The top of the figure shows an incoming virion that fuses with the plasma membrane to release the negative sense nucleocapsid in the cytoplasm. Viral messenger RNAs (mRNAs) are indicated by lines with the 5' mRNA cap denoted by a filled circle and 3' poly A tail by A_n . The gradient of decreasing molar abundance of the mRNAs from N to L owing to polar transcription is not illustrated. Also not illustrated is the relative abundance of genomic (negative sense) nucleocapsid versus antigenomic (positive sense) nucleocapsid. Solid lines denote primary and secondary transcription carried out by a P-L complex and genome replication carried out by an N-P-L complex. Dotted lines denote intracellular transport of nucleocapsid and M protein to the plasma membrane and the viral glycoproteins F, HN, and SH from the endoplasmic reticulum to Golgi to plasma membrane. The large arrow denotes release of progeny virions from the plasma membrane by a budding process.

© G.D. Parks and R.A. Lamb 2006

FIGURE 33.21. Paramyxovirus RNA synthesis. Viral nucleocapsids—the templates for RNA synthesis—are shown as a linear array of N subunits (ovals), with arrowheads indicating the gene junctions. Note that N protein binds six nucleotides, resulting in complete encapsidation of the RNA if it has a chain length that is an even multiple of six. The viral polymerase (P-L) transcribes the genome template, starting at its 3' end, to generate the positive leader RNA and the successive capped (meG-Cap) and polyadenylated (PolyA) mRNAs, by stopping and restarting at each junction. Once these primary transcripts have generated sufficient viral proteins, unassembled N (as a P-N complex) begins to assemble the nascent leader chain, and the coordinate assembly and synthesis of the RNA causes the polymerase to ignore the junctions, yielding the antigenome nucleocapsid (**bottom**). The P-L polymerase can also initiate RNA synthesis at the 3' end of the antigenome in the absence of sufficient P-N; however, only a 5' trailer RNA is made in this case. Note that positive leader RNA is not capped or polyadenylated and that genomic and antigenomic RNAs never appear as naked RNAs.

diagram indicating the differences between transcription and replication is shown in Figure 33.21. Unlike the situation for influenza viruses, *Paramyxoviridae* mRNA synthesis is insensitive to DNA-intercalating drugs such as actinomycin D,⁵⁹ and the *Paramyxoviridae* can replicate in enucleated cells.³¹⁶ In cell culture, single-cycle growth curves are generally of 14 to 30 hours duration but can be as short as 10 hours for virulent strains of NDV. The effect of viral replication on host macromolecular synthesis is quite variable, ranging from almost complete shut-off late in infection for NDV to no obvious effect with PIV5.

Virus Adsorption and Entry

For the respiroviruses and rubulaviruses, it has long been accepted that molecules containing sialic acid (sialoglycoconjugates) serve as cell surface receptors. This is based on the fact that sialidase of *Vibrio cholerae* acted as a “receptor destroying enzyme” and protected the host cell from infection.²⁴⁴ Sialic acid, the acyl derivative of neuraminic acid, is found on both glycoproteins and on lipids (sialoglycolipids or gangliosides). For Sendai virus, gangliosides function as both the attachment factor and the receptor for the virus.^{243,245,246} As described earlier, the cellular receptor for the *Morbillivirus* measles virus is the cell surface protein CD150 (SLAM), and the cellular receptor for pneumoviruses, although not proven, seems to involve binding to glycosaminoglycans containing the disaccharide heparan sulfate and chondroitin sulfate B.¹¹² On adsorption

of the virus to the cellular receptor, the viral membrane fuses with the cellular plasma membrane at the neutral pH found at the cell surface, the consequence of which is the release into the cytoplasm of the helical nucleocapsids.

In the virus particle, the M protein shell is thought to make numerous contacts with the nucleocapsid. On fusion of the viral envelope with the cell plasma membrane and release of the nucleocapsid into the cytoplasm, a mechanism needs to exist to disrupt the M-N contacts. With influenza A virus, the factor that alters the equilibrium between self-assembly and disassembly is thought to be the difference in pH between the acidic uncoating compartment (endosomes) and the assembly site (plasma membrane). The driving force for paramyxovirus uncoating is not known.

Viral RNA Synthesis

Paramyxoviruses have evolved mechanisms to control both the level and type of viral RNA that is synthesized during the course of an infection, largely through the use of *cis*-acting RNA sequences. The relationship between RNA sequences and the vRNAP functions that they control is particularly complex, because these *cis*-acting signals are only recognized when they are in the context of the nucleocapsid structure (see Fig. 33.21). Paramyxoviruses also encode *trans*-acting accessory proteins that control activities of the viral RNA. Recently, experimental systems have been developed that reconstitute RNA synthesis from model synthetic minigenomes using cDNA-derived

viral components, allowing the functional analysis of *cis*-acting sequences or *trans*-acting proteins.

Viral Transcription (Messenger RNA Synthesis)

Early in virus infection, before the viral translation products have accumulated to high levels (or in the presence of drugs that inhibit protein synthesis at any stage of the infection), vRNAP is restricted to the production of leader RNAs and mRNAs from the incoming virion nucleocapsid in a growth phase called *primary transcription* (see Fig. 33.20). At later times following infection, this input nucleocapsid is used as a template to produce positive sense antigenomes that in turn are used as templates to produce new negative sense genomic RNA. When abundant progeny genomes have been produced, they can serve as additional templates in the growth phase, called *secondary transcription*, to produce much higher levels of viral mRNA transcripts (see Fig. 33.20).

The paramyxovirus RNAP is thought to gain access to the viral genes through a single entry site at or near the 3' end of the genome. For the *Paramyxovirinae*, the *N* gene is transcribed as the first coding gene, and more than 90% of vRNAP that have initiated the Sendai virus *N* mRNA complete transcription of the entire *N* mRNA.⁴²⁰ This processive vRNAP responds to the *cis*-acting sequences at the end of the *N* gene (open triangles in Fig. 33.21) to produce capped and polyadenylated viral mRNAs. The vRNAP then reinitiates mRNA synthesis at the start site of the next downstream gene (closed triangles in Fig. 33.21), and this sequential “stop-start” mechanism continues across the viral genome in a 3' to 5' direction.

The viral gene junctions that modulate transcription can be divided into three segments: a GE region at the 3' end of the upstream gene, the IG region between the two genes that is normally not transcribed, and a GS region for the downstream 5' gene (see Fig. 33.5). The GE region contains a signal directing the vRNAP to terminate transcription and a stretch of four to seven uridine residues (U tract) that acts as a template for polyadenylation of the nascent mRNA by a mechanism that involves stuttering by the vRNAP. After termination of transcription, the vRNAP is thought to remain attached to the template as it moves across the IG nucleotides. Reinitiation of transcription is directed by sequences at the downstream GS site, which also directs the addition of a methylated 5' guanine cap to the nascent mRNA. The frequency of reinitiation is not perfect, and not every vRNAP that terminates at a GE remains on the template to reinitiate transcription at the next GS. This imperfect reinitiation frequency leads to a gradient of mRNA abundance that decreases according to distance from the genome 3' end, with *N* mRNAs being found in higher abundance than *L* mRNA.⁵⁰ Initiation at a downstream GS site depends on termination at the upstream GE site,²⁰⁸ consistent with a single entry site for the vRNAP at the 3' end of the genome.

In addition to synthesizing monocistronic mRNAs, the vRNAP can also ignore the GE sequences for polyadenylation/termination and synthesize a transcriptional read-through product that consists of a fusion of the upstream and downstream mRNAs. While read-through transcription is generally an infrequent event, for several paramyxoviruses, such as HPIV types 1 through 3, measles virus, and PIV5, read-through transcription is highest at the M-F junction, and approximately 50% to 80% of the F mRNA is locked into an M-F read-through product.^{27,49,334,380} An extreme example of this is seen

with simian virus 41 (SV41), where the M mRNA is seen exclusively as an M-F read-through product owing to a deletion of the M GE,⁴¹³ and F mRNA is found in both mono- and dicistronic forms.⁴¹⁴ The basis for this elevated M-F read-through for some paramyxoviruses is owing to GE insertions³⁸⁰ or substitutions³³⁴ that alter the efficiency of termination signals. The selective pressure to maintain elevated M-F read-through for some paramyxoviruses is not known but could reflect a need to increase access of a transcribing polymerase to the more 3' distal genes (e.g., HN or L) or a mechanism to down-regulate F protein expression, as this ORF would be locked into a dicistronic mRNA that would presumably not be translated.^{190,334}

Paramyxoviruses can be divided into two groups based on whether the viral GE and IG sequences are highly conserved across the genome or have a high degree of variability. The GE and IG regions of Sendai virus, HPIV1, and HPIV3 have a high degree of genetic conservation.²⁰³ For example, each of the Sendai virus GE sequences consist of a 3'-AUUCU₅-5' motif, and the IG region is 3'-GAA-5' (except the HN-L junction, which is 3'-GGG-5'). By contrast, the GE and IG regions of RSV, human parainfluenza virus type 2 (HPIV2), mumps virus V, SV41, and PIV5 are highly diverse and provide an additional level of transcriptional control beyond that which results from the distance of a gene from the 3'-end promoter. This diversity is reflected in the combinations of GE and IG sequences that can act together to differentially control vRNAP activities.^{144,333} RSV GE sequences are more diverse than their GS sequences and operate at variable efficiency in transcription termination and read-through.^{142,207} Moreover, for RSV, the L GS sequence is actually located upstream of the GE sequence of the upstream *M2* gene⁶⁵ (see Fig. 33.4). Thus, the RSV polymerase terminates at the *M2* GE; however, it is thought to scan backward on the template to reinitiate at the upstream L GS site.¹⁰⁸

Trans-acting viral proteins can also contribute to the control of stop-start transcription. For example, the RSV M2-1 protein is an essential transcription elongation factor that is necessary for high processivity of the vRNAP.⁶³ M2-1 can also modulate vRNAP activities at the diverse gene junction sequences,¹⁴² resulting in junction-specific changes in transcriptional read-through versus termination and in the relative abundance of mono- and dicistronic mRNAs.

P Gene Messenger RNA Editing

Pseudo-templated addition of nucleotides, popularly known as RNA editing, is a mechanism for obtaining more coding potential from a gene, and it was first identified for PIV5.^{307,408} It is now known that most paramyxovirus *P* genes contain a functional editing site within the coding region of the *P* gene (see Fig. 33.6). In addition to a faithful (unedited) mRNA, transcription across of the *P/V/C* gene yields edited versions that contain variable numbers of inserted G residues. The number of G insertions can differ for each virus group and mirrors their requirements for mRNAs that encode the individual P/V/W/I/D proteins (see Fig. 33.6). For the morbilliviruses, respiroviruses, and NDV, a single G is added to transcripts as the predominant editing event, resulting in an mRNA that shifts from the genome-encoded P ORF to the V ORF (see Fig. 33.6). For the rubulaviruses, which encode the V ORF as the unedited faithful copy of the *P/V* gene, the insertion of 2 Gs constitutes a high proportion of editing events, producing an

mRNA that encodes the P protein subunit of the vRNAP. For BPIV3 and HPIV3, where both the V and D ORF overlap the middle of the genome-encoded P ORF, one to six G residues are added at roughly equal frequency so that mRNAs encoding all three overlapping ORFs are transcribed.

As the paramyxoviruses replicate in the cytoplasm, they must provide enzymes for all aspects of their mRNA synthesis. Paramyxovirus vRNAPs polyadenylate their mRNAs by stuttering on a short run of template U residues (four to seven nucleotides long) at the end of each gene. By analogy to the polyadenylation mechanism, it was suggested that the G insertions at the specific site in the P gene would occur similarly by pseudo-templated transcription,⁴⁰⁸ and there is now strong experimental evidence that the insertions occur by a co-transcriptional stuttering mechanism.^{150,419} The efficiency of G insertion by the stuttering polymerase depends on the relative position of an editing site within the N-bound hexamer of nucleotides,^{181,203} suggesting that polymerase function is directed by a combination of RNA sequence and N protein structure within the template.

Genome Replication

A schematic diagram of transcription and RNA replication in the paramyxovirus growth cycle is shown in Figure 33.20, and the role of genomes and antigenomes as templates for these phases of RNA synthesis is shown in Figure 33.21. At early times of infection, the genome directs the synthesis of positive leader and viral mRNAs. After translation of the primary transcripts and accumulation of the viral proteins, the negative sense genome is replicated to produce a full-length complementary copy, called the *antigenome*, which is found only in a form that is assembled with N protein. Here, it is thought that the same vRNAP copies the same template that had been used for transcription, although now all of the gene junction signals (and editing sites) are ignored and an exact complementary copy of the template is generated. In infected cells, antigenomes are typically found in lower levels than genomes, and they do not code for any known functional ORFs or mRNAs. The sole function of the antigenome is thought to be as an intermediate in genome replication; however, the short trailer RNAs expressed from the antigenome 3' end (see Fig. 33.21) may also play a role in preventing the host cell from undergoing programmed cell death.¹⁸²

It has long been known that when infected cells are treated with drugs that inhibit protein synthesis, mRNA synthesis continues normally but genome synthesis is lost very quickly. As genome synthesis and encapsidation appear to occur concomitantly,¹³⁹ this requirement for ongoing protein synthesis during RNA replication is thought to reflect the need for a continued supply of unassembled N for genome encapsidation. Similar to the model for vesicular stomatitis virus (VSV), this coupling of genome assembly and synthesis also leads to a self-regulatory system for controlling the relative levels of viral transcription and replication. Because the leader sequences contain the N encapsidation site, the leader must be separated from the body of the first mRNA (by termination and reinitiation at the leader-N junction) to prevent the first mRNA from ending up in an assembled and untranslatable form. Thus, when unassembled N is limiting, such as early times in the growth cycle, vRNAP is preferentially engaged in mRNA synthesis, and this results in an increase in intracellular levels of all the

viral proteins, including unassembled N. When unassembled N levels are sufficiently high, some vRNAP would be switched to replication, thereby lowering the levels of unassembled N, as each initiation of encapsidation would commit approximately 2,600 N monomers to finish the assembled genome chain.⁴²⁰ The level of unassembled N may not be the only mechanism controlling transcription versus RNA replication, because higher levels of N protein have not affected the ratio of replication to transcription for RSV minigenomes.¹¹⁰

Paramyxoviruses employ additional mechanisms to control genome and antigenome replication, including the expression of viral accessory proteins that are not essential for virus growth but play a role in control of viral RNA synthesis. For example, the Sendai virus V protein is thought to inhibit RNA replication through binding to N⁰, the assembly-competent form of nucleocapsid protein.¹⁶⁸ The RSV M2-2 protein appears to play a role in regulation of transcription versus replication,¹⁴ and the RSV NS1 protein is a potent inhibitor of RNA replication in a minigenome system.⁶

After synthesis, the antigenomic RNA is used as a template to direct synthesis of genomic RNA by a mechanism similar to that for antigenome synthesis, in that the promoter at the 3' end of the antigenome directs synthesis of the short trailer RNA, also referred to as negative leader (see Fig. 33.21). Under conditions of sufficient intracellular concentrations of unassembled N (and perhaps other viral proteins), encapsidation of the nascent trailer chain would quickly begin and lead to the synthesis of encapsidated minus-strand genomes. As shown in Figure 33.20, these progeny negative sense genomes can serve three subsequent functions: as a template for mRNA synthesis in a phase called *secondary transcription*, as a template to produce additional antigenomes, or for incorporation into progeny virions during the budding process.

Paramyxovirus Replication Promoter

The 3'-end promoter in the antigenome directs the synthesis of progeny genomes and is thought to be a stronger promoter for RNA replication than the genomic 3'-end promoter in the genome that directs the synthesis of both mRNAs and antigenomes (see Fig. 33.21). Thus, the relative strength of genomic and antigenomic promoters in RNA replication can contribute to the relative ratio of these full-length RNAs in infected cells.²²¹ Extensive mutagenesis studies with model minigenomes have identified three factors that contribute to promoter function: the rule of six chain length requirement, nucleotide sequences within the bipartite promoter, and proper spacing of promoter elements.

It was found that changes in the overall length of a paramyxovirus N-RNA complex can profoundly affect the efficiency of RNA replication.⁴⁰ This RNA chain length requirement, called the *rule of six*, dictates that efficient replication of a viral genomic or antigenomic RNA will only occur when the total number of nucleotides in the RNA is an even multiple of six.⁴³ This surprising requisite is thought to reflect the precise nature with which the genomic RNA must be encapsidated by N to form a nucleocapsid template for the viral polymerase.^{43,315} The hexamer requirement emerged from microscopy studies of Sendai virus nucleocapsids, which revealed that each Sendai virus N molecule contacts six bases of RNA.¹⁰¹ During replication, N-RNA assembly is thought to initiate with the 5' end of the nascent RNA chain as it emerges from the vRNAP

complex, and encapsidation proceeds in a 5' to 3' direction.^{139,420} As shown schematically in Figure 33.21, a genome whose length is an even multiple of six nucleotides will be precisely encapsidated by N, with no unencapsidated nucleotides protruding from the 3' end of the nucleocapsid.³¹⁵

There is large variability in the stringency to which various groups of paramyxoviruses adhere to the rule of six requirement. Sendai virus RNA replication highly depends on the rule of six,⁴³ whereas there is no replicative advantage to RSV genome analogs having genome lengths that are a multiple of any particular integer.³⁵⁰ RNA replication for PIV5, NDV, and HPIV3

is most efficient for 6N-length genomes, although this is not as stringent a requirement as found for Sendai virus.^{95,242,273}

The rule of six was originally proposed to reflect the need to have a functional nucleocapsid template with a precisely encapsidated 3' end and no "dangling" free bases. However, extensions to the 3' end of Sendai virus DI RNAs do not result in a decrease in RNA replication, regardless of whether these extensions were multiples of six or not.⁴²⁵ As shown in Figure 33.22B, an alternative hypothesis emerged by the observation that the phase of a particular base in the promoter can range from position 1 to 6 within a hexamer of N-bound sequences.

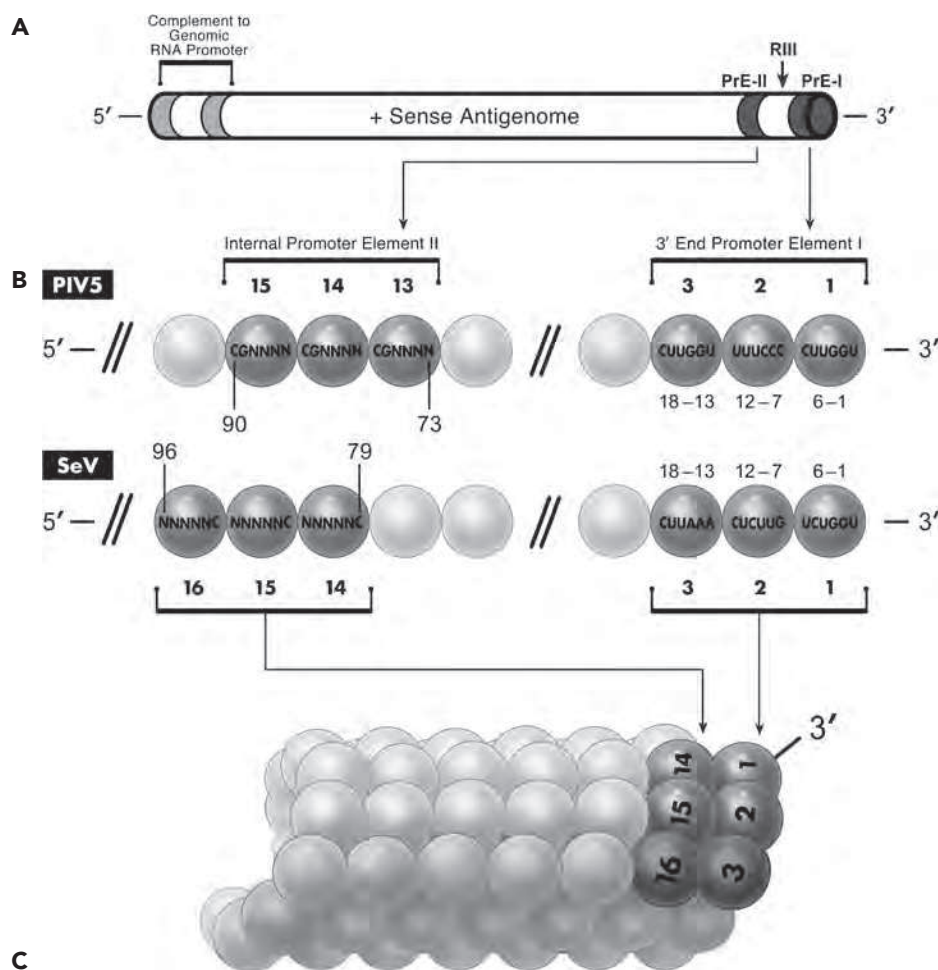

FIGURE 33.22. Nucleocapsid structure, hexamer phasing of nucleotide sequences, and the bipartite replication promoters of the Paramyxovirinae. **A:** Schematic of the paramyxovirus positive sense antigenomic RNA. The location of the 3'-end promoter element I (PrE-I) and internal promoter element II (PrE-II) are indicated by shaded areas, with location of the intervening nonessential region III replication element (RIII) shown by an arrow. The 5' end of the antigenome contains sequences that are the complement to the genomic RNA promoter and are partially complementary to the 3' region of the antigenomic RNA. **B:** Expanded view of a portion of the first 16 N protein subunits (drawn as ovals) of the antigenome nucleocapsid. Numbers above the ovals indicate the position of each N monomer, and numbers below the ovals refer to the nucleotide sequence relative to the 3' end of the RNA. The position of nucleotides within the 3'-end PrE-I and internal PrE-II elements for parainfluenza virus type 5 (PIV5) and Sendai virus are shown relative to the N subunits, with each subunit containing precisely six nucleotides. Note that for the internal PrE-II element, essential C residues are located in the first position of each hexamer for Sendai virus, whereas GC residues are located in the fifth and sixth positions for PIV5. **C:** A model for the Sendai virus and PIV5 nucleocapsid as an assembly of single N protein subunits (shaded spheres), in the form of a left-handed helix with N binding six nucleotides and 13 N subunits per turn. Numbers refer to the position of each N subunit from the RNA 3' end. Note that both PrE-I and PrE-II of the bipartite replication promoter are found on the same face of the helix.

Experimentally altering the predicted phase of nucleotides in the antigenomic promoter reduces RNA replication.³¹⁵ This finding is consistent with a model for the rule of six requirement based on critical *cis*-acting promoter sequences that can only be recognized when they are in the correct positions within their encapsidating N monomers.²⁰³ Further support for this hypothesis comes from the finding that the Sendai virus promoter can function when located at an internal position in a viral N-RNA complex, but only when the hexamer phase of promoter elements is correct.⁴²⁵

A second primary determinant of replication promoter strength resides in the nucleotide sequence in the leader RNA at the 3' terminus of the genome and in the trailer complement RNA at the 3' terminus of the antigenome.^{164,242,272,400,401} As shown in Figure 33.22, two discontinuous sequence-specific elements have been identified within the 3'-terminal 90 bases of the antigenomic promoter. In the two original descriptions of this requirement, these elements have been termed conserved region I (CRI) and conserved region II (CRII) for PIV5^{272,274} and promoter element I (PrE-I) and promoter element II (PrE-II) for Sendai virus.⁴⁰⁰

PrE-I is located at the 3' end of viral genomic and antigenomic RNA (see Fig. 33.22), and the specific sequence is highly conserved between members of a paramyxovirus genus. The internal PrE-II sequence is located within the L gene for the antigenomic promoter or within the N gene for the genomic promoter.^{164,272,400,426} Paramyxoviruses fall into two groups based on the distance of their critical PrE-II bases from the 3' end of the viral RNA and the sequence and the position of essential bases within an N hexamer. As diagrammed in Figure 33.22B, the internal PrE-II element for PIV5 and related rubulaviruses is located between 72 and 90 bases from the 3' end of the viral RNA.²⁷² By contrast, the PrE-II element for Sendai virus and related respiro- and morbilliviruses is located between 79 and 96 bases from the 3' end.^{400,426} The sequence requirements within PrE-II are remarkably simple; however, they differ for PIV5 and Sendai virus RNA replication. For PIV5, extensive mutational analyses²⁷⁴ indicated that the PrE-II requirements consisted of a CG motif located in the first two positions of three sequential hexamers of nucleotides (5'-CGGGAU CGAUGG CGAGAA-3', template sense, see Fig. 33.22B). By contrast, the Sendai virus PrE-II requirements consisted of three copies of a 5'-(NNNNNC)-3' motif (see Fig. 33.22B; shown as template sense). An additional element located between antigenomic PrE-I and the internal PrE-II has been identified for PIV5 (bases 51–66) and HPIV3 (bases 13–55), which is thought to act as a nonessential enhancer of replication.^{164,196}

A third factor in RNA replication was identified during mutational analyses of the PIV5 and Sendai virus antigenomic promoters, where it was found that deletions or insertions in the RNA segment located between the 3'-terminal PrE-I and the internal PrE-II resulted in templates that were not competent for RNA replication.^{272,400} The template defect was not attributed to disruption of an important *cis*-acting segment or the rule of six. As described in the next section, it is thought that the sensitivity of RNA replication to changes in the length of the region between PrE-I and PrE-II reflects a requirement for these two RNA segments to align to the same face of the nucleocapsid template.^{274,400}

Image reconstruction of electron micrographs indicates that Sendai virus N binds six nucleotides and that 13 N mon-

omers constitute a turn of the nucleocapsid helix.¹⁰¹ Together with extensive mutational analysis of minigenome analogs, these data suggest a model for the paramyxovirus promoters.^{220,272,400} As shown in Figure 33.22B,C, nucleotides within the 3' PrE-I and internal PrE-II elements are separated along the linear RNA sequence by 55 to 60 bases; however, in the N-encapsidated form, these RNA elements are aligned to the same face of the nucleocapsid template by the helical winding. Alignment of PrE-I and PrE-II may form a binding site for the polymerase complex to initiate RNA synthesis at the 3' end of the template, although formal proof of this hypothesis is not currently available. Taken together, the available evidence indicates that promoter strength is a major factor dictating level of RNA replication, and promoter strength is in turn affected by (a) changes in the phase of nucleotides within the N-induced hexamer phase of PrE-I or PrE-II (rule of six requirement); (b) changes in the RNA sequences themselves; or (c) changes in the spacer region between PrE-I and PrE-II, which alter their alignment on one face of the nucleocapsid template.

Virion Assembly and Release

Paramyxoviruses, like other enveloped viruses, are formed by a budding process. Buds emerge from sites on the plasma membrane where viral components have assembled, then pinch off resulting in the release of particles. Assembly of paramyxoviruses is thought to require coordinated localization of multiple but distinct virus components, including viral glycoproteins, which are transported to the plasma membrane by the exocytic pathway, and soluble viral components, such as the RNP. This coordination appears to be accomplished through a series of protein–protein and protein–lipid interactions, many of which involve the viral matrix protein that could potentially interact with both glycoproteins via their cytoplasmic tails and with the RNPs in the cytoplasm of the infected cell, and also interactions between viral components and the host machinery that allows bud formation and membrane fission. Those *Paramyxovirinae* that have NA activity contain glycoproteins that lack sialic modification of their carbohydrate chains, and it is thought that the HN NA activity serves the same purpose as NA of influenza virus—to prevent self-binding and to prevent reattachment to the infected cell.

Assembly of the Nucleocapsid

Nucleocapsids assemble in the cytoplasm in two steps: first, association of free N subunits with the genome or template RNA to form the helical RNP structure, and second, the association of the P-L protein complex.¹⁹⁹ By analogy to the mechanism of assembly of TMV nucleocapsid, which uses a defined nucleation site for the association of the first coat protein subunit with the RNA, and the observation that the paramyxovirus mRNAs are not encapsidated in contrast to antigenomes, it has been assumed that the positive leader (5' end of the antigenome) and negative trailer (5' end of the genome) regions contain specific sequences for initiating encapsidation.¹⁹

Assembly of the Envelope

The assembly of the second part of the virus—the envelope—is at the cell surface. In polarized epithelial cells, the *Paramyxovirinae* bud only from the apical surface. For a long time, it has been thought that the matrix proteins of negative-strand RNA viruses have important roles in virus assembly and budding.

Matrix proteins are positioned in virions beneath the lipid envelope, so that they have the potential to contact both RNP cores and envelope glycoprotein cytoplasmic tails, and are therefore likely to be the key organizers of virus assembly that induce separate viral components to concentrate together at defined budding sites on the plasma membranes of infected cells. Matrix proteins bind to viral RNPs *in vitro* and are found stably attached to RNPs when purified from virions, they bind to lipid membranes both *in vitro* and in living cells, and they self-assemble into ordered structures as purified proteins *in vitro* and in virus-infected cells. Studies using reverse genetics techniques have aided in understanding the role of the matrix protein in assembly. The M proteins of measles virus and Sendai virus had previously been implicated in budding based on analysis of viruses derived from persistent viral infections. Cells persistently infected with Sendai virus were found to express an unstable M protein, and lack of stable M protein correlated with a reduction in virus particle formation.³⁴¹ A role for the measles virus M protein in budding was suggested based on analysis of viruses isolated from patients with SSPE. SSPE viruses are defective for the production of progeny virus particles. Nucleotide sequence analysis has revealed extensive defects in the M genes of SSPE measles virus strains.^{53,440} Recombinant measles viruses were generated having defective or deleted M genes.^{45,309} Both of these viruses were shown to be severely defective in budding; Indeed, the infectivity was so low that the particles may represent adventitious vesicles with RNPs.

The Use of Virus-like Particles to Study Assembly

The importance of the matrix protein for virus budding has been investigated using the assembly of VLPs from proteins expressed from cDNAs. For PIV5, although M protein expressed by itself does not induce efficient budding of particles, when M is co-expressed with N protein and a viral glycoprotein (either F or HN), budding of particles becomes very efficient, approaching the budding efficiency observed in virus-infected cells.³⁵⁹ VLP budding that is normally observed on expression of the Sendai virus M protein alone can be made more efficient by co-expressing the Sendai virus F glycoprotein.³⁹⁵

Glycoprotein Cytoplasmic Tails and Assembly

It has long been thought that the glycoprotein cytoplasmic tails would be used in recognizing the M protein. Early studies using a temperature-sensitive mutant of Sendai virus (ts271) demonstrated that the Sendai virus HN protein is dispensable for budding of virus particles.^{326,328,387,415} VLP budding was observed on expression of M protein alone and the efficiency of budding was found to be stimulated on co-expression of F protein; however, co-expression of HN protein had no effect on budding efficiency.³⁹⁵ Recombinant Sendai viruses with altered glycoprotein cytoplasmic tails have been generated, and truncation of the F protein cytoplasmic tail resulted in poor budding. Release of particles on expression of F protein alone was found to depend on the amino acid sequence TYTLE, comprising amino acids 542 to 546 of the F protein cytoplasmic tail.³⁹⁵ Recombinant PIV5 were recovered harboring HN proteins with truncated cytoplasmic tails, and budding was found to be inefficient on HN protein cytoplasmic tail deletion.³⁵⁷ The same approach was used to define the role of the PIV5 F protein cytoplasmic tail in virus budding, and it was found that recombinant viruses with deleted F protein cytoplasmic

tails replicated in tissue culture and were released from infected cells with similar efficiency to wild-type virus.⁴²⁹ This result was surprising in light of work with Sendai virus suggesting that F protein is in fact quite important for proper paramyxovirus budding. To investigate further the relative roles of the HN and F glycoproteins for paramyxovirus budding, a VLP system was developed for PIV5.³⁵⁹ Here, efficient budding of VLPs from transfected cells was observed only on co-expression of multiple PIV5 proteins. Thus, expression of M protein alone did not lead to substantial particle budding, and neither of the PIV5 glycoproteins was found to have an autonomous exocytosis activity. However, co-expression of M protein with N protein and either the HN or F glycoprotein led to budding of VLPs with an efficiency comparable to that found in virus-infected cells. Budding decreased more than 25-fold when neither of the PIV5 glycoproteins were included, and the HN and F proteins were found to be completely interchangeable for VLP budding. This result suggested that the two PIV5 glycoproteins might have redundant functions for budding. Consistent with this idea, recombinant PIV5 lacking both HN and F protein cytoplasmic tails was found to have a greater defect in particle production and release than PIV5 lacking only the HN protein cytoplasmic tail.⁴²⁹ From VLP experiments, the importance of the glycoprotein cytoplasmic tails for efficient budding was confirmed; VLPs containing wild-type HN or wild-type F as the only glycoprotein bud efficiently, whereas those containing only cytoplasmic tail-deleted HN or cytoplasmic tail-deleted F protein bud poorly.³⁵⁹ SSPE measles virus strains contain drastic sequence alterations not only in their M genes, as discussed previously, but also in their F protein cytoplasmic tail sequences.⁵² Truncations or other alterations to the F protein cytoplasmic tail led to more rapid and extensive cell-to-cell fusion of virus-infected cells, consistent with a shift in the mode of virus spread to one that is independent of budding.^{46,263} Very recently, for RSV, it was shown that a critical phenylalanine residue in the F protein cytoplasmic tail mediates assembly of internal viral proteins into viral filaments and particles.³⁶⁹

Budding and Interactions with the Multivesiculate Body Formation Machinery

For several enveloped viruses, it has been shown that budding occurs in a way that requires the manipulation of host machinery. Protein-protein interaction domains called *late domains* have been defined in retroviral Gag proteins and in the matrix proteins of some negative-strand RNA viruses. These late domains function to recruit host factors to viral assembly sites where they assist in virus release.^{117,265} Disruption of viral late domains often leads to phenotypes in which virus particles assemble normally but fail to be released by membrane fission and instead accumulate as tethered particles on cellular membranes.^{83,127,135,184}

Several types of late domain have been identified: P(T/S)AP, PPxY, and YP(x)_nL. Each of these late domain sequences likely functions to bind with a different host factor to facilitate virus budding. P(T/S)AP late domains mediate binding to TSG101,^{127,248} and the host partner protein for YP(x)_nL late domains appears to be AIP1.^{247,383,421,424} Both TSG101 and AIP1 are part of the cellular vacuolar protein sorting (VPS) pathway (ESCRT) that allows formation of multivesicular bodies (MVBs), an observation that is significant owing to the fact that virus budding and vesicle budding into MVBs are similar

processes, in which cytoplasmic cargo is packed into vesicles that bud outward from the cytoplasm. PPxY-type late domains have been shown to interact with WW domains from a variety of proteins, such as Nedd4-related E3 ubiquitin ligases.^{146,197,411} It has been proposed that recruitment of Nedd4 family members may allow indirect recruitment of other host proteins, including those involved in MVB formation.³⁸⁴

Budding of PIV5 and PIV5-like particles was reduced by treatment of cells with the proteasome inhibitor MG-132.³⁵⁸ Proteasome inhibitors also reduce virus budding of retroviruses such as HIV-1³⁶³ and RSV³⁰⁸—viruses that use PTAP and PPxY late domains for budding. Inhibition of proteasome function prevents recycling of ubiquitin that is attached to proteins targeted for degradation, thereby depleting free ubiquitin levels in the cell.⁴²³ It has been found that the PIV5 M protein is targeted for monoubiquitination in transfected cells at three lysine residues. Mutation of the lysine residues leads to altered ubiquitination and impaired VLP production. Analysis of these mutations in recombinant viruses suggest that monoubiquitination of PIV5 M protein is needed for virus assembly and budding.¹⁴⁵

There have been several attempts to discover cell proteins that interact with viral proteins during budding. Production of PIV5 and PIV5-like particles is reduced on expression of a dominant-negative VPS4A adenosine triphosphatase (ATPase).³⁵⁸ Interestingly, substantial incorporation of the dominant negative VPS4A mutant into VLPs was noted, despite the relatively small amount of VLPs produced under these conditions. VPS4 mutants disrupt the cellular MVB formation pathway, likely because adenosine triphosphate (ATP) hydrolysis is required for release of class E proteins from late endosomal membranes. The PIV5 M protein lacks previously defined late domains (e.g., P[T/S]AP, PPxY, YPDL) to recruit cellular factors. However, a new late domain for budding (core sequence FPIV) that can compensate functionally for lack of a PTAP late domain in budding HIV-1 VLPs was identified.³⁵⁸ Mutagenesis experiments suggested the more general sequence Ø-P-x-V. The proline residue was found to be critically important for function of this late domain, as substitution of this proline in PIV5 M protein resulted in poor budding of PIV5 VLPs and failure of recombinant PIV5 virus to replicate normally. Adaptation of mutant virus harboring an altered FPIV domain occurred rapidly, resulting in new proline residues elsewhere in the M protein.³⁵⁸ Yeast two-hybrid screening identified angiomin-like 1 (AmotL1) as a host factor that interacts with PIV5 M protein. Overexpression of M-binding AmotL1-derived polypeptides potently inhibited production of PIV5 VLP budding and small interfering RNA (siRNA)-mediated depletion of AmotL1 reduced PIV5 budding.³¹³ Yeast two-hybrid screening also identified a protein designated as 14-3-3 as a binding partner of PIV5 M, and it was found that 14-3-3 negatively affects virus particle formation.³¹⁴ However, it is not known if AmotL1 and 14-3-3 are involved in the ESCRT pathway.

For Sendai virus, a sequence YLDL has been found in the M protein that acts as a late domain and is required for budding.¹⁸⁰ Curiously, YLDL of Sendai virus M protein is not replaceable by other late domains, perhaps because of structural constraints. It has been found that the Sendai virus M late domain interacts with the N-terminus of the cellular protein Alix/AIP1, a component of the ESCRT pathway. Mutagenesis of M protein YLDL to ALDA abolished budding and the interaction with

Alix/AIP1. A revertant virus was obtained with the sequence ALDV, and budding was restored together with the interaction of the M protein with Alix/AIP1.¹⁷⁹ The Sendai virus C protein also interacts with Alix/AIP1, and C protein expression enhances budding. It is thought that C protein recruits Alix/AIP1 to the plasma membrane and enhances the efficiency of the utilization of the ESCRT machinery for efficient VLP budding.

Budding of Paramyxoviruses from Membrane Rafts

It has recently become clear that lipid molecules within the plasma membrane are not distributed homogeneously in each leaflet of the bilayer, but rather participate in lateral associations to form subcompartments within the membrane. One type of lipid microdomain is the membrane raft, which preferentially contains sphingolipids and cholesterol as well as certain integral membrane proteins.^{34,372} Membrane rafts can be separated biochemically from other membrane components based on their resistance to solubilization by certain nonionic detergents such as TX-100 at low temperatures. Some viral proteins have been found to be enriched within membrane rafts of infected cells, suggesting that virus assembly can occur on rafts. For example, in influenza A virus-infected cells, the glycoproteins hemagglutinin and NA, as well as the matrix protein, are found associated predominantly with TX-100-insoluble lipids.^{223,339,340,374,454} Assembly of viral proteins on raft membranes does not appear to be a universal strategy for negative-strand RNA virus assembly, however, as in the cases of VSV and rabies virus infections, the viral proteins are found excluded from raft membranes in the infected cells. Paramyxovirus proteins in many cases have been found to be associated with raft membranes in infected cells, including the HN and F glycoproteins of Sendai virus,³⁵¹ F and HN proteins of NDV,^{90,210} the measles virus proteins H, F, M, and N,^{239,422} and the RSV glycoproteins F and G.³⁶

Polarized Budding from Epithelial Cells

The paramyxoviruses Sendai virus, PIV5, and measles virus have been found to bud preferentially from the apical membranes of polarized cells.^{18,338} Polarized budding may have important consequences for viral pathogenesis, as budding from the apical surface could favor restriction of the infection to the epithelial cell layer, whereas budding from the basolateral surface allows viral access to underlying tissue and could favor development of a systemic infection. Consistent with this view, Sendai virus and PIV5 both produce localized infections of the respiratory tract *in vivo*, whereas VSV and Marburg virus both produce systemic infections *in vivo*. Furthermore, a mutant Sendai virus has been characterized in which polarized budding from the apical membrane is lost and virus is instead released in a nonpolar fashion from both the apical and basolateral cell surfaces, and this virus causes a systemic infection and is more virulent than wild-type Sendai virus.⁴⁰³ The correlation between pathogenicity and virus budding from the basolateral cell surface is not absolute, however, because measles virus is released apically yet produces a systemic infection *in vivo*.

MOLECULARLY ENGINEERED GENETICS (REVERSE GENETICS)

The study of viruses and their interactions with host cells and organisms has benefited greatly from the ability to engineer

FIGURE 33.23. Rescue of paramyxoviruses from cloned complementary DNA (cDNA). Nonsegmented negative-strand virus rescue involves the transfection of plasmids encoding the viral P, N, and L proteins (and sometimes other viral proteins depending on the virus), as well as the viral antigenome, all under control of the T7 promoter. The bacteriophage T7 RNA polymerase is provided by either infection with a vaccinia virus expressing T7 polymerase (in this case, modified vaccinia virus Ankara, MVA-T7) or by transfecting into cell lines that stably express the protein (e.g., BSR-T7 cells). pT7-SV5 contains a complete copy of the parainfluenza virus type 5 (PIV5) genome (15,246 nucleotides) and is flanked at one end by a bacteriophage T7 RNA polymerase (T7 RNAP) promoter and at the other end by a hepatitis delta virus ribozyme and T7 transcriptional terminator. The plasmids pT7-L, pT7-P, and pT7-N each contain the cDNA for the PIV5 L, P, and N proteins, respectively, under the control of T7 RNAP promoters such that messenger RNA transcripts encoding L, P, and N can be transcribed using T7 RNAP. (Adapted from He B, Paterson RG, Ward CD, et al. Recovery of infectious SV5 from cloned DNA and expression of a foreign gene. *Virology* 1997;237:249–260.)

specific mutations into viral genomes—a technique known as reverse genetics.⁴³⁴ For RNA viruses, genome manipulation of the positive sense RNA bacteriophage Q β was the first to be performed.³⁹⁸ The negative-stranded RNA viruses, in contrast to positive sense RNA viruses, require that the virion RNA is assembled into an active transcriptase-replicase complex in order for the genome to initiate virus replication. Nonetheless, techniques to manipulate the genomes of nonsegmented negative-strand RNA viruses have now been developed.³³⁵ The development of the system originally proved quite frustrating. Several laboratories studying various rhabdoviruses and paramyxoviruses worked over a period of several years to establish the methods of reconstructing functional nucleocapsids from transfected cells. The concept of replicating minigenomes using support plasmids providing N, P, and L proteins in *trans* was key to the development of the technology. This culminated

in the successful recovery of infectious rabies virus in 1994, followed several months later by VSV, and several months later by Sendai, human RSV, and measles virus.

Rabies virus was rescued when plasmids encoding L, P, and N protein, as well as a plasmid containing the viral antigenome, all under control of the bacteriophage T7 RNAP promoter, were transfected into cells infected with a recombinant vaccinia virus expressing the bacteriophage T7 RNAP protein (vac-T7).³⁶¹ As an example, the following viruses have been rescued: VSV,^{219,436} measles virus,³³² human RSV,⁶² Sendai virus,^{126,194} rinderpest virus,¹¹ HPIV3,^{93,163} PIV5 (SV5),¹⁵⁴ NDV,³¹² and bovine RSV.³⁹ A schematic diagram showing the general scheme for rescue is illustrated for PIV5 in Figure 33.23. Some refinements to the original technique have been made, such as the use of stably transfected cell lines expressing the bacteriophage T7 RNAP (in lieu of vac-T7 infection), or one or more of the viral proteins required for genome replication.^{39,332}

VIRAL ACCESSORY GENES AND THEIR INTERACTIONS WITH THE HOST

Type I IFN is one of the most important antiviral cytokines that can be a major determinant of tropism, pathogenesis, and viral dissemination. As shown in Figure 33.24, the cellular IFN response involves two general phases: the induction of IFN synthesis in a primary transcriptional phase and signaling through the type I IFN signaling pathway to activate a secondary transcriptional phase (see Chapter 8).¹⁶ A large body of work has emerged recently on the role of paramyxovirus accessory proteins in counteracting the host cell IFN pathways at the level of IFN synthesis or IFN signaling.^{70,122}

Antagonists of Interferon Synthesis

As shown in Figure 33.24, synthesis of IFN- β can be induced by by-products of virus replication such as viral double-stranded RNA (dsRNA) or 5'-triphosphate RNAs, which are recognized by cellular pattern recognition receptors (PRRs). These PRRs include the dsRNA-activated protein kinase R (PKR), toll-like receptors (TLRs), and two cytoplasmic RNA helicases retinoic acid inducible gene-I (RIG-I), and melanoma differentiation-associated gene 5 (MDA5).^{3,446} Many PRRs signal through a mitochondrion-associated protein called *mitochondrial antiviral signaling protein* (MAVS) or IFN- β promoter stimulator 1 (IPS-1)¹⁹⁵ to activate cytoplasmic kinases including TANK-binding kinase 1 (TBK-1)/inhibitor of κ B kinase ϵ (IKK ϵ). Ultimately, this leads to dimerization and phosphorylation of latent transcription factors such as NF κ B and members of the family of interferon regulatory factors (IRFs), which can translocate to the nucleus and activate cellular promoters that drive expression of IRF responsive genes such as IFN- β . Results from transfection assays and the study of viruses that have been engineered to encode altered or deleted genes have identified viral antagonists of pathways that lead to IFN- β induction. These antagonists include the respirovirus and morbillivirus V and C proteins, the rubulavirus V protein, and the henipavirus V and W proteins.^{24,153,204,320,337,370,377} The pneumovirus NS1 and NS2 proteins also limit induction of IFN- β and are discussed elsewhere in this text.^{230,377}

For many paramyxoviruses, PKR is not activated to a large extent during infection except in the case where viral

FIGURE 33.24. Interferon (IFN) induction, IFN signaling, and sites of antagonism by paramyxovirus accessory proteins. Schematic diagram of IFN induction (**left**), binding of IFN to extracellular receptors (**top and middle**), and signal transducers and activators of transcription (STAT)-mediated signaling (**right**) to activate transcription from cellular genes containing an interferon-stimulated response element. Sites of inhibition by a paramyxovirus antagonist are indicated by two wavy lines or by an open arrow.

antagonist proteins such as V and C proteins are altered.^{21,251,391} In the case of these viral mutants, PKR activation results in a global inhibition of both viral and cellular translation, and there is an amplification of IFN- β synthesis.²⁵¹ Expression of wild-type viral proteins *in trans* can in some cases suppress activation of the PKR. These results have been interpreted by some as evidence that the V and C proteins directly inhibit PKR activation. A more likely mechanism is that the wild-type proteins act to control viral RNA synthesis, which is deregulated in the case of the mutants, and this indirectly prevents PKR activation.^{21,251,391} This is further supported by the finding that PKR activation by a PIV5 P/V mutant is suppressed by expression of the wild-type P protein—a component of the viral RNAP with no known antiviral activity.¹¹⁹

The V protein has been shown to be an inhibitor of MDA-5-mediated IFN production for numerous paramyxoviruses.¹³¹ The highly conserved V protein Cys-rich domain is both necessary and sufficient (in transfection experiments) for V protein to limit dsRNA-induced activation of the IFN- β promoter.^{204,320} This inhibition is thought to occur through direct interaction of V protein with multiple sites on MDA-5, a competition with dsRNA for MDA-5 binding, and an inhibition of MDA-5 multimerization to the active form.³ Despite this well-documented inhibition, MDA-5 can still contribute to IFN induction *in vivo*.¹²⁹ In the case of Nipah virus, both V and

W proteins can block IFN- β promoter activation. This inhibition may result from targeting of different steps in the IFN induction pathway or different cellular sensors, because Nipah virus V and W proteins appear to localize to the cytoplasm and nucleus, respectively,³⁷⁰ and the W protein completely lacks the Cys-rich C-terminal domain found in the V protein.

In addition to targeting MDA-5, V proteins from a select group of paramyxoviruses have been reported to also act as a decoy substrate for the cellular kinases IKK ϵ /TBK-1 (in the case of rubulaviruses²³³) or IKK α (in the case of measles virus³¹⁷), resulting in a second mechanism for blocking activation of IRF-3 and IRF-7 through a range of PRRs. This would predict that rubulaviruses would have the potential to inhibit many cellular pathways, including TLR3, TLR4, RIG-I, and other activators of IRFs that depend on TBK-1. While intriguing, this would be inconsistent with previous work showing that PIV5 is unable to block signaling through TLR3 and TLR4⁵ and that RIG-I function is very likely also not blocked in PIV5-infected cells.²⁴¹ An interesting possibility is that these kinases are targeted in a cell-type-specific manner, as evidenced by the finding that V protein acts as a decoy for IKK α kinase to facilitate measles virus inhibition of IRF-7 in plasmacytoid cells.³¹⁷ The measles virus V protein is reported to bind to the p65 subunit of NF κ B³⁶⁴; however, it is unclear how widespread this is among other paramyxoviruses.

The C proteins that are expressed by some but not all paramyxoviruses can play a role in blocking IFN responses through mechanisms distinct from that of V protein.²⁸¹ Stable cell lines expressing the Sendai virus C proteins have reduced capacity to activate the IFN- β promoter in response to dsRNA.²⁰⁴ Sendai virus, measles virus, and HPIV1 mutants that are defective in C (or Y) protein expression are strong inducers of the IFN- β promoter.^{21,204,251} Whereas some data support a model whereby the C proteins directly block IFN induction,^{33,204,385} other studies indicate that C proteins modulate the viral polymerase to limit production of dsRNA^{21,391} and thus indirectly limit IFN induction. This latter model is supported by the finding of high levels of dsRNA in cells infected with C protein mutants compared to infections with wild-type virus.^{21,391} Inhibition of IFN- β synthesis by the measles virus C protein appears to depend on the ability of C protein to shuttle between the cytoplasm and nucleus,³⁷⁸ suggesting an additional mechanism to limit IFN- β transcription.

There is relatively little current available data on the role of RNA-activated TLRs in IFN responses to paramyxovirus infections. The Nipah virus W protein appears to block TLR3 signaling through a mechanism that depends on nuclear localization.³⁷⁰ Measles virus has been shown to block TLR7- and TLR9-mediated IFN production from human plasmacytoid dendritic cells³⁵⁶ through V protein targeting the cellular kinase IKK α to inhibit IRF-7 phosphorylation.³¹⁷ By contrast to the inhibition seen by measles virus, PIV5 is a potent activator of IFN- α secretion in human plasmacytoid dendritic cells through a mechanism that depends on TLR7 signaling and autophagy pathways.²⁴⁰

Antagonists of Interferon Signaling Pathways

As shown in Figure 33.24, IFN signaling is initiated when secreted IFN binds to its receptor on the cell surface, resulting in the phosphorylation of latent transcription factors STAT1 and STAT2 (signal transducers and activators of transcription) by the cellular Janus kinases (JAK) Tyk2 and Jak1. STAT1 and STAT2 heterodimerize and associate with IRF-9 to form the transcription factor ISGF3, which translocates to the nucleus to bind to interferon-stimulated response elements (ISRE) located in the promoter region of IFN-inducible genes.^{16,171} Paramyxoviruses employ a remarkably diverse range of mechanisms to circumvent IFN signaling.^{172,448}

For some paramyxoviruses, the V protein blocks IFN signaling by targeting one of the STAT proteins for degradation: the PIV5, mumps virus, and SV41 V proteins target STAT1 degradation, whereas the HPIV2 V protein directs STAT2 degradation.^{4,88,172,448} V-dependent targeting of STAT to the proteasome involves the assembly of a cytoplasmic ubiquitin ligase complex, which for PIV5 contains V protein, STAT1, STAT2, the ultraviolet (UV)-DNA damage repair binding protein DDB1, and a member of the Cullin family of ubiquitin ligase subunits.^{227,330,416,417} The PIV5 V protein specifically targets STAT1 and not STAT2 for degradation, although this STAT1 specificity requires the presence of the nontargeted STAT2 protein.²⁹⁸ PIV5 V protein degradation of STAT1 occurs in human cells but not mouse cells, and PIV5 growth in mouse cells is restricted.⁸⁸ However, efficient STAT1 degradation and higher PIV5 replication levels can be restored in mouse cells engineered to express human STAT2.²⁹⁸ Similarly, PIV5 replicated to higher levels in lungs of transgenic mice that were

engineered to express human STAT2.²⁰⁶ A single amino acid substitution in the PIV5 V protein N-terminal domain is sufficient to allow targeted degradation of mouse STAT1, leading to a block in IFN signaling.⁴⁴⁷ Thus, the ability to assemble specific STAT degradation complexes and disrupt IFN signaling may be a factor in determining the host range of some paramyxoviruses such as PIV5 and NDV,^{298,299} which can be restricted for growth in cells from particular species.

IFN signaling is blocked by some paramyxoviruses through mechanisms that do not involve targeted degradation, but rather by binding of V to STAT proteins and preventing phosphorylation or transport to the nucleus. For example, the Hendra virus and Nipah virus V proteins induce the formation in the cytoplasm of high molecular weight complexes consisting of STAT1, STAT2, and IRF-9,³³⁷ and these underphosphorylated complexes are unable to function in signaling. The Nipah virus V and W proteins are both capable of blocking IFN signaling through binding to STAT1 but apparently do so in the cytoplasm and nucleus, respectively.³⁷¹ Nipah virus V protein can also bind to STAT2³³⁶; however, the importance of this binding relative to STAT1 interactions is not entirely clear. By a different mechanism, the measles virus V protein prevents IFN signaling by blocking translocation of both STAT1 and STAT2 into the nucleus,²⁹⁷ and cytoplasmic aggregates can be detected where STATs co-localize with nucleic acids and viral nucleocapsid protein. Remarkably, the measles virus P protein binds to STAT1 to prevent phosphorylation⁸⁷ through interactions involving a specific tyrosine residue that is associated with some attenuated vaccine strains.²⁹⁰

The respiro- and morbilliviruses utilize the C proteins to block IFN signaling,^{123,133,193,368} and viral C protein mutants can be highly attenuated for growth.^{94,124,310} Recent evidence indicates that in different experimental systems, the C proteins can alter STAT phosphorylation patterns,¹³³ can be detected as an interacting partner with STAT1,^{123,392} and can induce ubiquitination and degradation of STAT1 in some types of cells.¹²⁵ Thus, the mechanisms by which the C proteins block IFN signaling are not completely understood and may differ depending on a particular cell type and virus.

HISTORY

The four serotypes of human parainfluenza virus types 1 to 4 (HPIV1 to HPIV4) were first recovered between 1956 and 1960, following the application of cell culture and hemadsorption techniques to the study of pediatric respiratory tract disease.^{48,49,175} HPIV1, HPIV2, and HPIV3 were initially isolated from infants and children with lower respiratory tract illness (LRI), and HPIV4 was recovered from children and young adults with mild upper respiratory tract illness (URI). Soon after their discovery, these viruses were shown to be a major cause of croup (HPIV1, 2, and 3) as well as pneumonia and

bronchiolitis (HPIV3).^{45,115,283} As a group, HPIV1, HPIV2, and HPIV3 are second only to human respiratory syncytial virus (HRSV) as a cause of serious viral respiratory tract disease in infants and children, whereas disease due to HPIV4 is less frequent and less serious.

There also are a number of parainfluenza viruses (PIVs) that infect animals. Indeed, the first PIV to be identified was the avian pathogen Newcastle disease virus (NDV). This virus was isolated following outbreaks in 1926 in Java, Indonesia, and Newcastle-upon-Tyne, England, of a seemingly new poultry disease with high mortality.⁹¹ The origin of this then-emerging pathogen remains obscure. This virus, or a close progenitor, may have been indigenous in wild birds, and its appearance or evolution as a “new” disease entity may have been associated with the increasing scale of poultry farming at that time. Nine distinct serotypes of avian PIVs (now usually called avian paramyxoviruses, or APMVs) are now recognized, of which NDV constitutes serotype 1.⁵ Another PIV was recovered in 1952 in Japan from mice inoculated with an autopsy specimen from an infant with respiratory disease.^{216,264} The natural history of this virus, Sendai virus (SeV), is not well understood, but it appears to be a murine virus that is closely related to HPIV1 but is not a human pathogen. Its antigenic relatedness to HPIV1 led to some confusion when it was used in serologic studies of patients with acute respiratory disease. Bovine parainfluenza type 3 (BPIV3), a close bovine relative of HPIV3, was isolated in 1959 from cattle with respiratory tract disease called shipping fever.^{1,2} PIV5, previously known as simian virus 5 (SV5), was first isolated in 1954 as a common contaminant of primary monkey kidney tissue cultures (hence its name).¹⁶³ This was at a time when these cultures were being used to prepare poliovirus vaccine material, and a number of new viruses were recovered and identified from the primary tissue. PIV5 was shown to be related to HPIV2 and was identified as a cause of croup (“kennel cough”) in dogs.^{21,22,44} Simian virus 41 (SV41) was isolated in 1961, also as a contaminant of primary monkey kidney cell culture.²⁵¹ SV41 was found to be even more closely related to HPIV2 than PIV5.³⁷⁷ Therefore, there are four known human PIVs (HPIV1–4) and 13 known animal PIVs (SeV, BPIV3, PIV5, SV41, NDV/APMV1, and APMV2–9). This number may increase: virus that appears to represent a 10th APMV serotype was recently isolated from penguins from the Falkland Islands.²⁵⁰

The name *parainfluenza* originally was coined because some of the disease signs are influenza-like and because, like influenza, the particle is medium-sized, has a lipid envelope, and has hemagglutination and neuraminidase activities. This name was first used in 1959 for the four viruses now known as HPIV1, HPIV2, HPIV3, and SeV.¹⁰ Therefore, the term parainfluenza refers to the four serotypes of HPIV and their

close animal relatives, and also includes the APMVs, even though these lack close human relatives. Another common human virus, mumps virus (MuV, Chapter 35), is related to the PIVs (most closely to HPIV2) and shares their physical and morphologic properties, but its hallmarks of parotitis and orchitis render it distinct.

Because they can readily be grown to high titer, the animal PIVs SeV, PIV5, and NDV have been used extensively in studies spanning several decades that have defined many of the basic molecular and biological properties of Family *Paramyxoviridae*; this information is described in detail in Chapter 33.

The present chapter focuses on PIV biology and in particular the HPIVs.

INFECTIOUS AGENT

Classification, Relationships, and Diversity

The PIVs are enveloped, cytoplasmic viruses (Fig. 34.1) with single-stranded, nonsegmented, negative-sense RNA genomes of 14.9 to 17.3 kb (Fig. 34.2). They are distributed among three genera (namely *Respirovirus*, *Rubulavirus*, and *Avulavirus*)

FIGURE 34.1. Schematic diagram (A) and electron photomicrographs (B–G) of parainfluenza virus (PIV) virions.

A: Idealized diagram of a PIV virion, not to scale and not intended to imply relative molar amounts or exact spatial relationships. The V protein (not shown) is found as a structural protein only in *Rubulavirus*.²⁸⁴ The C protein (not shown) of the *Respirovirus* Sendai virus (SeV) also has been reported to be present associated with the virion nucleocapsid (not shown).⁴⁰³ **B:** PIV5 virions budding from the surface of a cultured cell.⁵⁸ Intact **(C)** and disrupted **(D)** HPIV2 virions that were fixed and negatively stained; envelope spikes can be seen in both **C** and **D**, and the helical nucleocapsid is evident in **D**.¹⁵⁶ (continued)

of subfamily *Paramyxovirinae*, family *Paramyxoviridae*, order *Mononegavirales*.²¹⁸ (The other subfamily is *Pneumovirinae*, which contains HRSV, human metapneumovirus [HMPV], and their relatives). HPIV1 and HPIV3, and their respective murine and bovine relatives SeV and BPIV3, constitute the genus *Respirovirus* (Fig. 34.3). HPIV2, its relatives PIV5 and SV41, and HPIV4 are part of the genus *Rubulavirus*. *Rubulavirus* is a diverse genus that also contains related viruses that are not considered PIVs, such as MuV, Mapuera virus, and porcine rubulavirus. The various APMV serotypes constitute the genus *Avulavirus*.

The relationships between the PIVs are illustrated in Figure 34.3 by alignment of the amino acid sequences of the L proteins. Representative viruses from *Morbillivirus* and *Henipavirus*, two other genera of the subfamily *Paramyxovirinae*,

are included for comparison. This shows that the PIVs as a whole are broadly divergent and are not clearly demarcated by sequence relatedness as a group distinct from the non-PIV members of *Paramyxovirinae*. This comparison also shows the close relatedness between some of the human and animal PIVs, such as between HPIV1 and SeV and between HPIV3 and BPIV3. It is likely that these closely related viruses arose from transmission across host species.

The relationships between the PIVs also are illustrated in Tables 34.1 to 34.3 by the percent amino acid sequence identity for the two major surface antigens, namely the fusion F glycoprotein (Table 34.1) and the hemagglutinin-neuraminidase HN glycoprotein (Table 34.2), as well as for the large polymerase L protein (Table 34.3). This illustrates, for example, that the HPIV serotype distinctions are associated with

PIV, parainfluenza virus; HPIV, human parainfluenza virus; SeV, Sendai virus; BPIV, bovine parainfluenza virus; SV41, Simian virus 41; NDV, Newcastle disease virus.

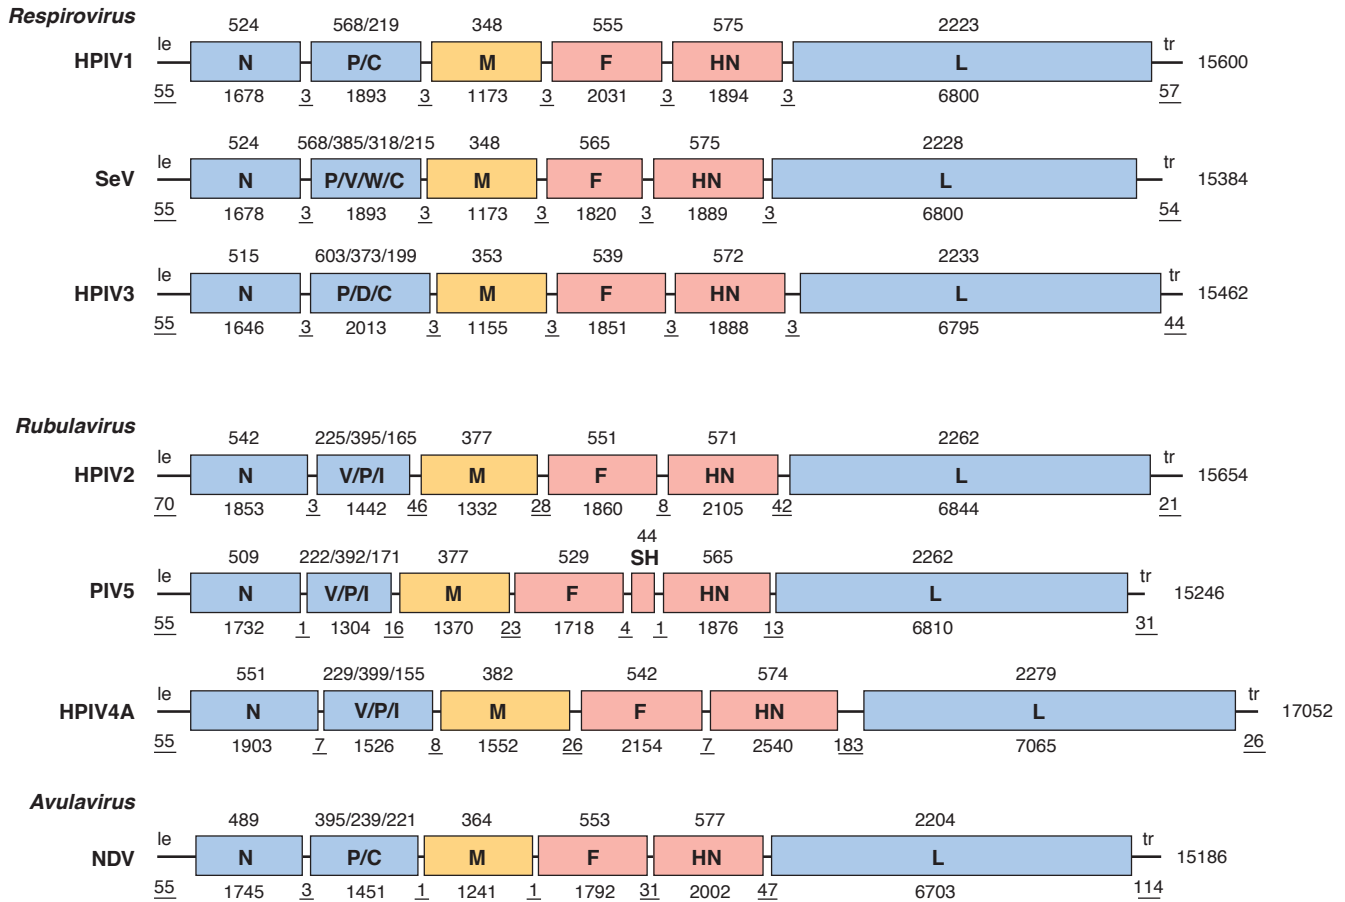

FIGURE 34.2. Gene maps of selected parainfluenza viruses (PIVs), not to exact scale. Each negative-sense genome is drawn 3' to 5', which is the direction of transcription. Genes are shown as rectangles: those encoding nucleocapsid-associated and accessory proteins are in blue; those encoding the transmembrane surface glycoproteins are in red; and those encoding the matrix protein of the inner envelope are in brown. The letters within each rectangle identify the encoded protein(s); for P and V, the protein encoded by the unedited messenger RNA (mRNA) is shown first. Nucleotide lengths are shown under each diagram; those representing the extragenic leader (le), trailer (tr), and intergenic regions are underlined. Amino acid sequence lengths are shown above the diagrams. The maps are generally similar, and there is general similarity in genome, gene, and protein lengths, although some differences exist: (a) the P and V proteins are encoded by unedited and edited mRNA, respectively, for *Respirovirus* and *Avulavirus*, whereas for *Rubulavirus* the situation is the converse; (b) there are differences among the PIVs in other proteins encoded by P gene; (c) PIV5 and APMV6 (the latter not shown here) have the additional SH gene; (d) the intergenic regions of *Respirovirus* are conserved trinucleotides, whereas those of the other genera are variable; (e) the P proteins of *Rubulavirus* and *Avulavirus* are shorter compared to those of *Respirovirus*; and (f) human parainfluenza virus 4 (HPIV4) has a substantially longer genome. Maps are based on the Washington/1964 strain of HPIV1 (NC_003461), the Z strain of Sendai virus (SeV) (M30202), the JS strain of HPIV3 (X11575), the V94 strain of HPIV2 (AF533010), PIV5 (NC_006430), the Toshiba/M-25/1966 strain of HPIV4A (AB543336), and the LaSota strain of Newcastle disease virus (NDV) (AF077761).

amino acid sequence identities of less than 50% for F and HN. The APMV serotypes are not shown in these tables, but they also usually (but not always) have less than 50% amino acid sequence identity between F and HN of the different serotypes.^{43,172,213,214,265,318,353,401,402} For example, the percent amino acid sequence identity between APMV5 versus serotypes 1, 2, 3, 4, 6, 7, 8, and 9 is, respectively: 41, 47, 31, 33, 55, 37, 46, and 37 for the F protein; and 35, 42, 33, 30, 56, 43, 41, and 31 for the HN protein.³¹⁹

Antigenic reactivity based on binding assays can be detected between PIVs within a genus with polyclonal sera and, less frequently, with monoclonal antibodies (MAbs).^{167,203,271} A lower

level of reactivity between genera sometimes is detected with polyclonal sera, although there is no group antigen encompassing the three PIV genera.

HPIV4 has been segregated into two variants, A and B, based on antigenic differences detected by hemadsorption-inhibition (HI) and MAb reactivity.²⁰⁴ Sequence analysis shows that these two subgroups are very closely related: the percent identity between the F, HN, and L proteins is 95, 87, and 97, respectively (Tables 34.1 to 34.3), and they likely would not be distinguishable in neutralization assays with postinfection sera. Variation within the other HPIV serotypes appears to be somewhat less. For HPIV2, the percent amino acid sequence

FIGURE 34.3. Phylogenetic analysis of the amino acid sequences of the L proteins of the parainfluenza viruses (PIVs) and other selected members of *Paramyxovirinae* (genera are indicated on the right). PIVs are boxed. The scale at the bottom indicates evolutionary distance as the number of substitutions per site. The analysis is based on the neighbor-joining method³¹³ and was performed with Molecular Evolutionary Genetics Analysis (MEGA)4.³⁶¹ The numbers at branch points indicate the percentage in which the associated taxa clustered together in the bootstrap test (500 replicates). The L protein sequence was chosen for analysis because it is one of the more conserved proteins, accounts for a substantial part of the viral coding sequence, and is similar in size for each virus. The sequences were as in Figure 34.2 or were from the following: avian paramyxovirus 2 (APMV2), EU338413; APMV3, EU403085; APMV4, EU877976; APMV5, GU206351; APMV6, EU622637; APMV7, FJ231524; APMV8, FJ215863; APMV9, EU910942; Mapuera virus, NC_009489; porcine rubulavirus, NC_009640; MuV, NC_002200; Simian virus 41 (SV41), NC_006428; BPIV3, NC_002161; SeV, NC_001552; CDV, canine distemper virus, NC_002728; MeV, measles virus, AF266288; HeV, hendra virus, NC_001906; NiV, Nipah virus, NC_001906. This analysis was kindly provided by Drs. Sachin Kumar and Siba Samal, University of Maryland at College Park.

identity between the V94 strain versus the V98 and Greer strains was, respectively, 98 and 99 for F, 95 and 96 for HN, and 99 and nearly 100 for L.³³⁷ For HPIV3, comparison of the F protein sequence of prototype strain Washington/47885/57 with seven clinical strains revealed 98% or more identity,⁶² and comparison of HN with six clinical strains revealed 97% or more identity.³⁸⁵ For HPIV1, comparison of 40 strains showed that the percent amino acid sequence identity for the HN protein was 95% or greater.¹⁴⁶ For NDV, comparison of 50 strains from various times and places of isolation showed that the percent identity between F and HN was 91% and 90% or greater, respectively.³¹⁷ Some of the other animal PIVs, such as APMV2,³⁵² APMV3,²¹⁴ APMV6,⁴⁰² and BPIV3,¹⁵² have been found to have somewhat greater diversity (i.e., intraserotype amino acid sequence identity for F and HN of 75% to 79% for APMV2, 70% to 73% for APMV3, 81% to 86% for APMV6, and 86% to 89% for BPIV3), resulting in distinct genotypes or subgroups within a serotype. In the case of APMV2, APMV3, and APMV6, this has been shown to be associated with a modest degree of antigenic difference detectable with postinfection sera.

NDV is notable because the many highly related naturally occurring isolates and strains that have been recovered for this single serotype exhibit a broad spectrum of virulence, ranging from nonvirulent or mildly virulent (lentogenic), to moderately virulent (mesogenic), to highly virulent (velogenic). Lentogenic strains are associated with subclinical infection or can cause mild respiratory tract disease, and the more attenuated natural isolates are used as live vaccines. At the other extreme, velogenic strains can be highly virulent and, depending on the strain, can cause hemorrhagic lesions in the intestines (viscerotropic) or neurologic disease (neurotropic).³¹⁷ In contrast, there is no evidence of differences in virulence among the various isolates of each of the four serotypes of HPIV, although this has not been studied extensively. Little is known about the possible diversity of disease within the other animal PIVs.

Virion Morphology and Activities

The virions of PIVs are medium-sized particles of 150 to 200 nm. Fixed, negatively stained virions typically appear in electron micrographs as pleomorphic (irregularly shaped) round particles (Fig. 34.1).^{58,156,253,324,369} Filamentous virions have been described in some cases, such as for HPIV2.⁴⁰⁵ Cryoelectron

microscopy of ice-embedded SeV and PIV5 provided images of virions as predominantly perfect spheres of varied diameters.^{153,233,369} This suggests that the irregular shapes of particles observed with conventional electron microscopy are artifacts of sample fixation and dehydration, whereas the variations in size were observed using both methods and thus may be authentic. Seventy-one percent of the ice-embedded PIV5 virions consisted of spheres of 129 to 360 nm (average 217 nm), and the remainder were elongated particles of up to 445 nm.³⁶⁹

PIVs replicate in the cytoplasm and bud through the plasma membrane (Fig. 34.1B). The virion consists of a nucleocapsid that is packaged in a lipid envelope derived from the host cell plasma membrane during budding (Fig. 34.1). In the nucleocapsid, the viral genome is tightly bound along its entire length with the nucleoprotein N at a ratio of one protein molecule per six nucleotides (2,484 to 2,877 protein molecules, depending on the length of the viral genome). Associated with the nucleocapsid in the virus particle are approximately 300 copies of the phosphoprotein P and approximately 40 copies of the major polymerase protein L, based on studies with SeV.^{200,219} *Rubulaviruse* virions contain an additional nucleocapsid-associated protein called V,²⁸⁴ and the virion of the *Respirovirus* SeV has been reported to contain 40 copies of a small protein called C, also associated with the nucleocapsid.⁴⁰³ Electron micrographs of nucleocapsids released from PIV virions indicate a length of approximately 1.0 to 1.1 μm .^{65,233} The nucleocapsid with its associated proteins has RNA-dependent RNA polymerase activity.¹³⁴ Purified virions can be activated for cell-free transcription by disruption of the envelope with detergent and can transcribe the viral genome in its entirety into messenger RNAs (mRNAs).⁶⁴

The envelope bears spike-like surface projections composed of homotrimers and tetramers of the F and HN glycoproteins, respectively. Based on cryoelectron microscopy, PIV5 virions were estimated to contain approximately 2,000 glycoprotein spikes per 200 nm particle, with an average spike length of 14.2 nm.³⁶⁹ PIV5 and APMV6 have a third, small transmembrane protein, SH ("small hydrophobic"). The nonglycosylated matrix M protein is associated with the inner surface of the envelope. The hemagglutination activity of the HN protein mediates adsorption of virus to the host cell to initiate infection. The cellular receptor for the PIVs is N-acetylneuraminic

acid (sialic acid) in a terminal linkage to cellular glycoproteins and glycolipids.^{356,411} In the case of HPIV3, cell surface nucleolin also has been reported to serve as a receptor co-factor.²⁹ Viral attachment can be measured experimentally by the agglutination of erythrocytes by virus in suspension (hemagglutination) or by the adsorption of erythrocytes to infected cell monolayers expressing HN (hemadsorption) as was used in the original detection of the HPIVs. Late in infection, the neuraminidase activity of HN cleaves sialic acid to facilitate release of progeny virions. Neuraminidase activity can be quantified using sialic acid derivatives as substrates in a colorimetric or fluorometric assay. The F protein mediates fusion between the viral envelope and the host cell plasma membrane, an activity that can be measured *in vitro* by lysis of erythrocytes (hemolysis).

RNA

The PIV genome is a single strand of negative-sense RNA that ranges in length from 14,904 (APMV2) to 17,262 (APMV5) nucleotides (nt). The differences in genome length between the different PIVs are mostly due to differences in the lengths of noncoding sequences rather than substantial differences in the lengths of open reading frames (ORFs). The PIV genome is not capped or polyadenylated. It contains, in 3′ to 5′ order: a short 3′ extragenic leader region of 55 nt (except in the case of HPIV2, for which the leader region is 70 nt), followed by six genes encoding the N, P, M, F, HN, and L proteins, followed by an extragenic trailer region of 21 to 291 nt (Fig. 34.2; note that the longest, 291-nt trailer region is that of APMV-3 and is not shown in this figure). Sequences of the leader regions of selected PIVs are shown in e-Fig. 34.1A. As noted below, the P gene also encodes one or more accessory proteins—namely C, V, W, I, and D—depending on the virus (Fig. 34.2). PIV5 and APMV-6 each contain a seventh small gene that is located between F and HN and encodes the SH protein. In the case of *Respirovirus*, the PIV genes are separated by intergenic (IG) regions that are conserved trinucleotides (usually 3′-GAA in genome-sense); in the case of *Rubulavirus* and *Avulavirus* the IG regions have nonconserved sequences of variable length (0 to 183 nt) (Fig. 34.2; also, see e-Fig. 34.1B for gene junction sequences of selected PIVs).

Transcription and RNA replication occur in the cytoplasm and follow the *Mononegavirales* model. Briefly, the genes are transcribed sequentially in their 3′ to 5′ order to yield separate nonoverlapping mRNAs that are polyadenylated, capped, and methylated. RNA synthesis also yields short nonpolyadenylated and noncapped transcripts of the leader and trailer regions. Transcription is guided by short conserved gene-start (GS) and gene-end (GE) transcription signals that flank each gene (see e-Fig. 34.1B for gene junction sequences of selected PIVs). For RNA replication, the polymerase ignores the GS and GE signals and produces a complete positive-sense copy of the genome that is called the antigenome. Like the genome, the antigenome is not capped or polyadenylated. Both the genome and antigenome are completely bound with N protein.¹⁹⁹ Encapsidation of nascent genomes and antigenomes is thought to drive chain elongation during RNA replication. The tightly encapsidated nature of the nucleocapsid likely shields the uncapped and nonpolyadenylated genome/antigenome from degradation. It also likely shields the genome/antigenome from recognition by the cytoplasmic helicases retinoic acid-inducible gene 1 (RIG-I) and Melanoma Differentiation-Associated protein 5 (MDA5),

which detect triphosphorylated RNA and double-stranded RNA (dsRNA) and initiate signaling to activate the cellular transcription factors interferon regulatory factor 3 (IRF3) and nuclear factor kappa B (NF-κB) to induce type I interferon (IFN) and proinflammatory cytokines. This also reduces activation of protein kinase R (PKR), which is triggered through dsRNA to activate NF-κB as well as to phosphorylate eukaryotic translation initiation factor eIF-2α and thereby inhibit translational initiation as part of host defense. As another example of how viral RNA can affect host cell responses, one of the products of SeV RNA replication is a 55-nt aborted RNA representing the 5′ trailer region that contains a U-rich sequence that inhibits apoptosis by binding to the proapoptotic factor T-cell intracellular antigen 1 related (TIAR).¹⁶⁶

The nucleotide lengths of the genomes and antigenomes of the PIVs (and of all of subfamily *Paramyxovirinae*) are even multiples of six. This property is essential for efficient RNA replication and is called the “rule of six”.^{199–200,201,337} This is thought to reflect an obligatory nucleocapsid organization in which each N protein monomer associates with exactly six nucleotides. In experiments to recover recombinant HPIV2 and HPIV3 viruses whose nucleotide lengths were designed to not be even multiples of six, the recovered viruses contained genomes that had mutated to conform to the rule.^{336,337}

Each PIV gene encodes—via transcribed mRNA—a single major protein, with the exception of the P gene that can encode additional proteins in two ways that are described briefly here and in greater detail for the HPIVs in e-Fig. 34.2. First, all of the PIVs in the genus *Respirovirus* contain a C ORF that initiates near the 5′ end of the P mRNA, closely overlapping the start of the P ORF. Depending on the virus, the C ORF has from one to four different translational start sites that are utilized to give rise to up to four carboxy-co-terminal C proteins. *Rubulavirus* and *Avulavirus* do not have a C ORF. Second, the P genes of most PIVs encode additional proteins by “RNA editing”.^{199,201,388} This involves the co-transcriptional insertion of 1 or more G residues into the nascent mRNA by polymerase stuttering at an editing motif midway along the P gene. An array of mRNAs is produced: they include the unedited form as well as subpopulations that contain 1, 2, or more G residues inserted at the editing site. The insertion of 1 G residue (or 3+1, and so on) or 2 residues (or 3+2, and so on) creates frameshifts that access ORFs in the two other reading frames. For the PIVs of *Respirovirus* and *Avulavirus*, the unedited mRNA encodes the P protein,^{286,348,388} and the addition of a single G by RNA editing fuses the upstream half of the P ORF to an internal ORF encoding a domain with a conserved cysteine-rich domain: the resulting protein is called V. The addition of 2 G residues fuses the upstream half of the P ORF to an ORF in the third reading frame: this downstream ORF encodes only a few added amino acids and results in a protein called W, except in the case of HPIV3 and BPIV3 in which the number of added amino acids is substantially more and the resulting protein is called D (e-Fig. 34.2). HPIV1 is an exception because it does not appear to engage in RNA editing.^{245,307} In addition, although HPIV3 does engage in RNA editing, the V ORF is separated from the editing site by two or more (depending on the strain) stop codons in the same reading frame that may preclude expression of V (see e-Fig. 34.2).¹⁰⁸ For the PIVs of *Rubulavirus*, the exact-copy mRNA encodes the V protein, whereas an edited version containing

two inserted G residues encodes P.^{192,208,276,342,370} An edited version containing one inserted residue encodes the I protein, which is the *Rubulavirus* equivalent of W. [See the ebook for more information on coding assignments and RNA editing.]

Several factors control the relative efficiency of transcription of the various PIV genes. As is typical for *Mononegavirales*, there is a gradient of transcription in which promoter-proximal genes are expressed somewhat more efficiently than promoter-distal genes.^{64,138} This is thought to be due to polymerase fall-off at the gene junctions.¹⁶⁸ However, with the exception of L, the gradient of expression is not continuous or steep; in the case of SeV, for example, the P, M, F and HN mRNAs accumulate at 0.30, 1.15, 0.61, and 0.38 times the level of N.¹⁴⁸ Accumulation of the L mRNA is much lower (0.02 that of N). Differences in transcription signals also influence transcription. In PIV5, the efficiency of transcription across the different gene junctions, measured by the relative level of expression of the downstream versus upstream gene, was found to vary over a fourfold range, indicative of regulation at the level of the termination/re-initiation at the gene junctions.¹³⁸ However, the HN-L junction was not associated with a particularly high level of fall-off.¹³⁸ This suggests that the low level of expression of L relative to the other genes is due to some other factor such as polymerase fall-off during L gene transcription or instability of the L mRNA.

A number of PIVs have evolved mechanisms for downregulating expression of the F gene. The M GE signal of HPIV3 contains an apparent eight-nucleotide insertion that causes increased M-F readthrough (see e-Fig. 34.1B).³⁴⁴ The M GE signal of PIV5 contains a single nucleotide substitution that has the same effect.³⁰⁰ In SV41, the M GE signal is lacking altogether and M is expressed solely as an M-F readthrough mRNA.³⁷⁶ Interestingly, the F gene of SV41 also is expressed as a monocistronic mRNA by initiation at its GS signal, but this occurs at a reduced level because the majority of the polymerase molecules are already engaged in reading across the M-F junction. In HPIV1, the same effect of increased production of M-F mRNA at the expense of monocistronic F mRNA

was observed, and studies with recombinant viruses mapped the effect to a combination of features, namely the intergenic sequence, the F GS signal, and the long upstream nontranslated region of the F gene.³¹ Therefore, various features in these different viruses result in the synthesis of an M-F readthrough mRNA at the expense of a monocistronic F mRNA. In these M-F readthrough mRNAs, the F ORF would not be efficiently accessed by ribosomes due to its internal position.²¹¹ Finally, SeV downregulates expression of its F gene by yet another mechanism, namely through a suboptimal GS signal.¹⁸⁸ Therefore, each of these strategies results in reduced expression of this fusogenic factor. In the case of SeV, this was shown to reduce the virulence of the virus.¹⁸⁸ It might be that, by reducing morbidity and mortality in the host, the virus increases its opportunities for shedding and spread.

Proteins

All PIVs encode six common proteins: N, P, M, F, HN, and L, all of which are essential for virus replication. All members encode at least one additional protein from the P gene (C, V, D, W, and I, depending on the virus). PIV5 and APMV-6 also encode a small hydrophobic transmembrane SH protein.

HN Glycoprotein

The PIV HN glycoprotein (Fig. 34.4) mediates attachment by binding to host cell sialic acid. This activity is responsible for the ability of the virus to agglutinate erythrocytes. HN also functions late in infection to cleave sialic acid residues on the virus and nearby cell surface proteins to facilitate release of progeny virions. The dual hemagglutinin/neuraminidase functions of HN appear to be modulated by halide ion concentration and pH.²⁴⁸ Hemagglutination activity appears to be favored by the halide ion concentration and pH of the extracellular environment, consistent with the role of HN in binding to extracellular receptors, whereas neuraminidase activity is optimal at lower pH and halide ion concentration, consistent with the role of HN in stripping sialic acid from newly formed

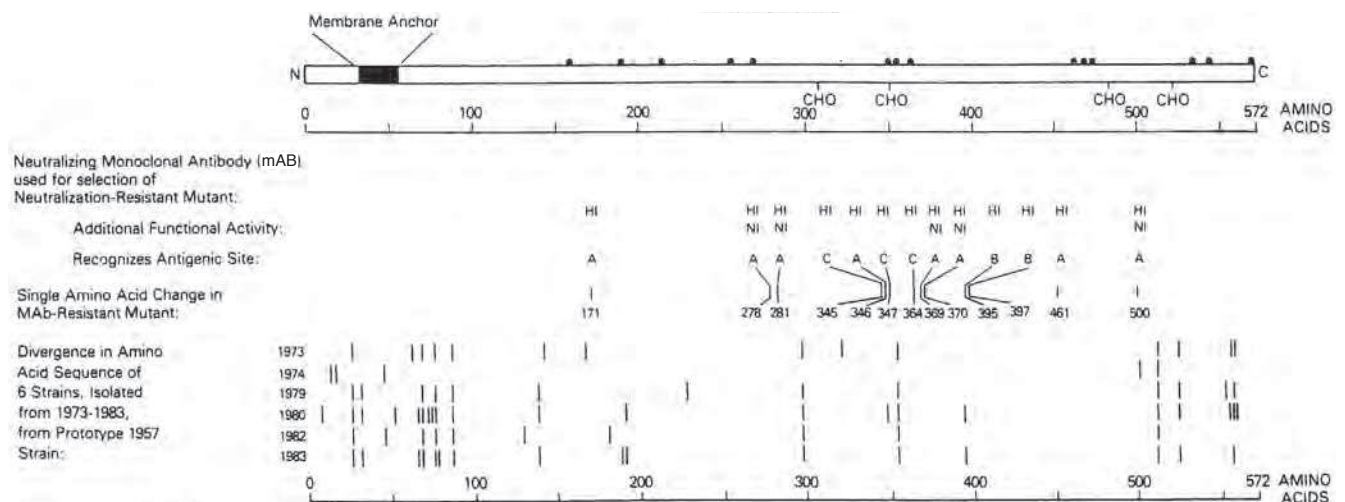

FIGURE 34.4. Linear diagram and antigenic organization of the human parainfluenza virus 3 (HPIV3) HN glycoprotein (strain 47885/5761). • Denotes cysteine; CHO denotes a potential site for N-glycan; HI (hemagglutinin-inhibiting) and NI (neuraminidase-inhibiting) denote positions of amino acid substitutions identified in neutralization-resistant mutants selected with HI and NI monoclonal antibodies (MAbs), and the amino acid positions and antigenic sites (A-C) are indicated; bars indicate positions of amino acid variability among natural isolates.

FIGURE 34.5. Linear diagram and antigenic organization of the human parainfluenza virus 3 (HPIV3) F protein (strain 47885/57⁶¹). • Denotes cysteine; CHO denotes a potential site for N-glycan; FI (fusion-inhibiting) denotes amino acid substitutions identified in neutralization-resistant mutants selected with FI MABs, and the amino acid positions and antigenic sites are indicated; bars indicate positions of amino acid variability among natural isolates.

viral and host cell glycoproteins in intracellular vesicles during transport to the cell surface. The HN proteins of PIVs and indeed most of *Paramyxovirinae* also play an essential role by interacting with the F protein to promote fusion.^{66,256,290,292,311}

HN is a type II glycoprotein that contains an uncleaved signal/anchor sequence located near the N-terminus (Fig. 34.4). HN assembles into homotetramers that contain a stalk that is sensitive to trypsin cleavage and a globular head that represents most of the extracellular domain. The globular head retains the HA and NA biologic activities and the major antigenic sites. On a gross level, the globular head has a box-shaped structure in which the four identical subunits exhibit fourfold symmetry. Crystal structures have been determined for the HN proteins of HPIV3, NDV, and PIV5, both free and complexed with its receptor or inhibitors^{32,69,222,312,409}; these are described in Chapter 33.

The HN protein of some avirulent strains of NDV is synthesized as a longer precursor, HN₀, in which the hemagglutinin and neuraminidase are inactive.^{263,316} Activation requires an endoproteolytic cleavage that results in the loss of a small, 9-kD glycopeptide from the carboxy terminus and a change in conformation.^{198,263} Like the F₀ precursor protein of the avirulent strains (see below), HN₀ is resistant to intracellular cleavage in most cell types and presumably is cleaved by extracellular secretory proteases, but unlike F₀ it does not have a marked trypsin-like specificity and can be activated *in vitro* by a variety of proteases.²⁶³ It might be that the shorter HN proteins of virulent NDV strains that lack this extension and do not require cleavage arose evolutionarily from longer cleaved ancestral ORFs by the introduction of translational stop codons. This is suggested by the finding that the ORFs of certain virulent NDV strains retain the apparent relic of an in-frame C-terminal extension beyond the nonsense codon terminating the current ORF.²⁴⁹ A counterpart to HN₀ has not been described for any

other PIV, although the sequence of the HN gene of HPIV4 has been interpreted as containing a relic of such an extension.¹³

F Glycoprotein

The fusion (F) glycoprotein (Fig. 34.5) mediates penetration of the host cell by fusion of the viral envelope to the plasma membrane. Late in infection, when newly synthesized F glycoprotein has accumulated on the surface of the infected cell, it also can mediate fusion with contiguous uninfected cells. This results in the formation of syncytia, a prominent cytopathic effect in monolayer cultures *in vitro*. At least in the case of SeV, the F protein also can act as an auxiliary attachment protein that binds to cells via the hepatocyte-specific asialoglycoprotein receptor,²⁴ although the significance of this *in vivo* is not known.

F is a typical type I glycoprotein (Fig. 34.5), with a cleaved N-terminal hydrophobic signal peptide and a C-proximal membrane anchor. The F protein is synthesized as an inactive precursor, F₀, which is converted into the fusogenic form by cleavage by a host endoprotease to yield two subunits: F₂, which contains the N-terminal 20% of the molecule, and F₁, which contains the remainder of the molecule and is anchored in the membrane. F₁ and F₂ remain linked by a disulfide bond.^{170,198} The F₁ amino terminus created by cleavage is a hydrophobic region called the fusion peptide that is thought to insert into the target membrane to initiate fusion. Crystal structures have been determined for the F proteins of HPIV3, NDV, and PIV5.^{52,357,406,407} The structure and function of F is described in detail in Chapter 33.

Cleavage of F₀ is a prerequisite for PIV infectivity and can be an important determinant of tissue tropism and pathogenesis for NDV and possibly other PIVs (see below and Pathogenesis and Pathology).^{262,374} Most velogenic (highly virulent) and mesogenic (moderately virulent) strains of NDV have a cleavage site with the sequence R/K-R-Q-R/K-R↓F (Table 34.4). This multibasic

TABLE 34.4 Cleavage Sites of the F₀ Proteins of Selected PIVs

Virus	Cleavage site sequence ^a							
HPIV1	Asp	Asn	Pro	Gln	Ser	Arg	↓	Phe
SeV	Gly	Val	Pro	Gln	Ser	Arg	↓	Phe
HPIV3 (prototype and five clinical isolates) ⁶²	Asp	Pro	Arg	Thr	Arg/Lys	Arg	↓	Phe
HPIV3 (two clinical isolates) ⁶²	Asp	Pro	Arg	Thr	Glu	Arg	↓	Ser
HPIV2 (prototype strains) ¹²	Thr/ Lys	Thr	Arg	Gln	Lys	Arg	↓	Phe
HPIV2 (nine clinical isolates) ¹²	Thr/Ala	Thr/Pro	Arg	Gln	Glu	Arg	↓	Phe
HPIV4	Ser	Glu	Ile	Gln	Ser	Arg	↓	Phe
NDV (virulent strains, consensus) ^{249,317,374}	Gly	Arg/Lys	Arg	Gln	Arg/Lys	Arg	↓	Phe
NDV (avirulent strains, consensus) ^{249,317,374}	Gly	Gly/Glu	Arg/Lys	Gln	Gly/Glu	Arg	↓	Leu

^aArg/Lys residues are bold, and Arg/Lys residues consistent with the preferred furin motif (Arg-X-Arg/Lys-Arg↓) are underlined. BPIV3, PIV5, and SV41 are not shown, but all contain the preferred furin motif. For the sources of the sequences, see the legends to Figures 34.2 and 34.3, references ^{26,62,158,202,247,346,367} and the other references cited in this table. PIV, parainfluenza virus; HPIV, human parainfluenza virus; SeV, Sendai virus; BPIV, bovine parainfluenza virus; SV41, Simian virus 41; NDV, Newcastle disease virus.

(basic residues are underlined) cleavage site conforms to the favored cleavage site R-X-R/K-R↓ for the ubiquitous intracellular protease furin,³⁰⁸ providing for efficient intracellular cleavage. Cleavage by furin or a furin-like protease allows the virus to replicate in cell culture without the need to supply exogenous protease in the culture medium. *In vivo*, it provides the potential for systemic spread and replication in a wide range of tissues, resulting in increased virulence. In comparison, the cleavage site sequence found in most avirulent NDV strains, G/E-K/R-Q-G/E-R↓, has fewer basic residues and does not conform to the furin cleavage site. These strains are not cleaved by furin and require added protease (typically trypsin or allantoic fluid added to the culture medium) for replication *in vitro*, and are restricted *in vivo* to mucosal tissue of the lungs or intestines where secreted protease capable of cleaving the F₀ precursor is found. Furin reportedly also may cleave at a “minimal” motif R-X-X-R↓,³⁰⁸ but apparently does not do so for the avirulent NDV strains.

Prototype strains of most of the PIVs have F₀ cleavage sites that contain the furin cleavage motif, including HPIV3, BPIV3, HPIV2, SV41, and PIV5 (examples are shown in Table 34.4), and these viruses do not require added protease for replication *in vitro*. On the other hand, the F₀ proteins of HPIV1, SeV, and HPIV4 lack the furin motif, and these viruses do require added protease *in vitro*. However, for viruses other than NDV, the lack of intracellular cleavage by furin does not necessarily indicate reduced virulence; for example HPIV1 and SeV can be highly virulent *in vivo* despite the lack of furin cleavage. Analysis of clinical isolates of HPIV3 showed that, although five of seven isolates contained the consensus furin motif observed in the prototype strains, two other isolates had the sequence D-P-R-T-E-R↓,⁶² which has the same arrangement of basic residues as avirulent NDV strains. However, these strains were fully competent for replication and the production of infectious virus *in vitro* without added protease, and did not exhibit any restriction for replication in the respiratory tract of rhesus monkeys. Similarly, several clinical isolates of

HPIV2 were found to have the cleavage site sequence T/A-T/P-R-Q-E-R↓,¹² which does not match the preferred furin motif. In this case, restricted growth by these clinical strains *in vitro* was observed in simian Vero cells but not in primary cultures of primate cells. Therefore, the presence of the preferred furin cleavage motif is not essential for intracellular cleavage or virulence in HPIVs.

Nucleocapsid-Associated N, P, and L Proteins

The N, P, and L proteins, together with the RNA genome, are the viral components that are necessary and sufficient to assemble the nucleocapsid and to direct transcription and RNA replication.^{94,134,365}

The N protein is one of the more conserved PIV proteins. It associates with genomic and antigenomic RNAs to form highly stable, RNase-resistant helical nucleocapsids. Monomeric N is maintained in a soluble complex with the P protein prior to assembly into nucleocapsids. The N-terminal 75% of N is the more highly conserved part and is involved in forming the soluble complex with P as well as in subsequently associating with other N monomers and with RNA to form the nucleocapsid. The more variable C-terminal 25% of the molecule is not required to form the nucleocapsid but is essential for it to function as a template.^{34,199}

The P protein is not highly conserved within a genus and has little or no significant sequence identity between genera. The P protein consists of N- and C-terminal functional modules separated by a divergent spacer that spans the RNA editing site.¹⁹⁹ P is found as a homotetramer.³⁶⁶ P is the most heavily phosphorylated viral protein, although the bulk of constitutive phosphorylation can be ablated by mutation in recombinant SeV without effect.¹⁵⁹ The N-terminal module of P is responsible for binding to free N protein and maintaining it as a soluble monomer necessary for nucleocapsid formation during RNA replication.^{74,149} The C-terminal module contains the homo-oligomerization domain and the polymerase co-factor domain, and is the only region of P necessary for transcription. This C-terminal module

mediates binding of P to the nucleocapsid. It also binds L protein and mediates its association with the nucleocapsid.^{149,199}

The L protein is a large multifunctional protein responsible for nucleotide polymerization and mRNA capping and methylation.²⁷⁵ The N-terminal half of L contains blocks of highly conserved amino acids that are thought to be polymerase domains.^{287,288} The L protein forms a complex with the P protein that appears to serve as the RNA polymerase.^{149,199}

The matrix M protein is a conserved, nonglycosylated species that is the most abundant virion protein and is located on the inner face of the virion envelope. In the infected cell, M associates with the inner face of the plasma membrane and plays key roles in virion assembly, budding, and release.^{326,360} Depending on the virus, expression of M alone (e.g., HPIV1) or together with N and HN or F (e.g., PIV5) triggers the formation and release of virus-like particles.^{67,354} The M protein of PIV5 was recently shown to contain a domain that mediates interaction with the host ubiquitin-proteasome pathway during the late stage of budding.³²⁶ M may also play a role in directing the transport of viral components to the plasma membrane.^{277,360}

Accessory C, V, D, W, and I Proteins

These are products of the P gene, and the various PIVs differ as to which of these proteins are expressed, with the general pattern being genus specific. These proteins are not essential for virus replication (and thus are termed accessory), although the C and V proteins in particular can substantially increase the efficiency of growth *in vitro* and *in vivo*. As noted, C is encoded by a separate ORF in the P gene of *Respirovirus*, and is not found in *Rubulavirus* or *Avulavirus*. The V, D, W, and I proteins are produced by various PIVs (see Fig. 34.2) by frame shifts introduced by RNA editing (except in the case of *Rubulavirus*, where the V protein is produced from unedited mRNA while P depends on editing). These proteins are summarized below, and additional information on the expression and functions of these proteins in HPIVs is in e-Fig. 34.2. (The complexity of the proteins encoded by the P gene is even greater for SeV, for which the last ~95 codons of the P ORF also are translated independently to yield a small nonstructural protein called X^{73,76}; this protein is almost equimolar to P in infected cells, but its function is unknown and it will not be considered further.)

The C protein is an abundant small basic protein whose sequence is not well conserved between viruses. C is expressed into one or more carboxy-co-terminal forms, depending on the virus, by utilization of one or more translational start sites in the ORF: for example, SeV and HPIV1 produce four C proteins (C', C, Y1, and Y2, in order of decreasing size), whereas HPIV3 produces one C protein (see e-Fig. 34.2). The different forms of the C proteins of SeV have been reported to have functional differences.^{75,111,112,220} C has historically been considered to be nonstructural, but the C protein of SeV was reported to co-localize with nucleocapsids in the infected cell and to be tightly associated with the virion-bound nucleocapsid, at 40 molecules per nucleocapsid.⁴⁰³ The functions of the C proteins have been investigated in detail for SeV. Deletion or mutation of the SeV C proteins results in strong induction of type I IFN and the establishment of an IFN-mediated antiviral state that restricts viral replication in IFN-competent cell culture and *in vivo*.^{110,215} The SeV C proteins were reported to inhibit activation of the transcription factors IRF-3 and NF- κ B that leads to induction of IFN- β .²⁰⁶ The C proteins also inhibit signaling

from the type I IFN receptor by binding to the signal transducer and activator of transcription protein 1 STAT1 and inhibiting phosphorylation of both STAT1 and STAT2.^{112,122,207,359} Another function of the SeV C proteins is to downregulate production of viral RNA at the level of transcription⁷⁵ and RNA replication.^{37,150,364} By preventing overly robust RNA synthesis, this regulatory activity appears to prevent the formation of dsRNA and unencapsidated triphosphorylated replicative RNAs during SeV infection, thus reducing activation of MDA-5/RIG-I and PKR involved in innate immunity.³⁵⁸ This regulatory activity also prevents the overproduction of antigenomes, which otherwise can result in the packaging of antigenomes into progeny virions that would be noninfectious.¹⁶⁵ The SeV C proteins inhibit apoptosis²⁰⁹ and have been reported to play a role in budding.^{136,315,354} Expression and functions of the C proteins of the HPIVs are described in e-Figure 34.2.

The V protein consists of the N-terminal half of P fused to a C-terminal V-specific domain that contains a sequence motif that is highly conserved in *Paramyxovirinae* and includes seven invariant cysteine residues (e-Fig. 34.2).^{140,272,299,322} The cysteine-rich domain has been shown to coordinate with two zinc atoms per protein molecule.^{227,284,347} V is a structural component of the nucleocapsid in the case of *Rubulavirus*, whereas V does not appear to be a structural component in *Respirovirus* virions and may be present in small amounts in *Avulavirus* virions.^{72,284,348} The clearest characterization of the functions of the V protein has come from studies with PIV5 and HPIV2, in which the absence of C protein facilitates evaluation. V has been shown to bind to MDA-5 and inhibit induction of IFN- β , whereas it did not appear to inhibit RIG-I.^{8,54,289,322} In addition, the V protein inhibits IFN-mediated signaling by mediating degradation of STAT1 or STAT2, depending on the virus and the host cell.^{9,161,272,320} PIV5-mediated degradation of STAT1 has been studied in detail and involves the V-protein binding to ubiquitin ligase and hijacking this cellular complex to target STAT1 for ubiquitination and proteasome-dependent degradation.^{85,227} The cysteine-rich domain must be present in order for V to inhibit IFN induction and signaling.¹⁴⁰ The V protein also delays apoptosis during viral infection,³⁵⁵ and downregulates viral transcription and RNA replication.²³⁰ The mechanism for the effect on RNA synthesis was studied with minireplicons of SeV and HPIV2 and was found to be different for the two viruses.^{151,270} With SeV, the presence of the N-terminal domain of P allows the V protein to bind to soluble N protein and thus interfere with nucleocapsid assembly,¹⁵¹ whereas with HPIV2, the inhibitory activity of the V protein was associated with binding to the L protein, and involved the unique C-terminal domain of V.²⁷⁰ The V protein of PIV5 also has been shown to slow progression of the cell cycle.²²⁸

Therefore, the PIV C and V proteins have a number of similarities in their general effects, even though they are completely distinct proteins that appear to operate by distinct mechanisms. Two major common functions involve interference with host innate immunity—especially the type I IFN response—and downregulation of viral RNA synthesis. These functions may be related: as noted above for the C protein, reducing viral RNA synthesis can reduce activation of MDA-5/RIG-I, PKR, and other sensors that trigger innate immunity. The V protein is particularly important for members of *Rubulavirus* and *Avulavirus* given their lack of C proteins. For *Respiroviruses*, which encode the potent C proteins, some of the

host-antagonist functions of the V protein may be redundant or less robust. For example, although the V protein of SeV has been shown to bind MDA-5 and inhibit induction of IFN- β ,^{53,54,206,289} the magnitude of this effect may be minor.^{123,314,350} Nonetheless, loss of expression of the SeV V protein significantly reduces the efficiency of viral replication *in vivo*, indicating a contribution that is additional to that of the C proteins.^{189,190} Exactly what this contribution is remains unclear.³¹⁴ For the human *Respiroviruses*, V is more dispensable: as noted, HPIV1 does not encode a V protein due to a lack of RNA editing and the presence of translational stop codons within the V ORF, and HPIV3 likely expresses, at most, only low levels of V due to the presence of stop codons upstream of the V domain (see e-Fig. 34.2 for details on the expression and functions of the V proteins of the human PIVs). The presence of relict V ORFs interrupted by stop codons suggests that predecessors of the present HPIV1 and HPIV3 expressed V proteins, but that this ability became compromised by mutations that introduced these stop codons. Their animal relatives, SeV and BPIV3, respectively, retain the ability to efficiently express V.

The W (present in SeV and *Avulavirus*), I (*Rubulavirus*), and D (HPIV3 and BPIV3) proteins are created when RNA editing fuses the upstream end of the P ORF to a short internal ORF in the remaining reading frame. In the case of W and I, this internal ORF adds only a few amino acids; in the case of the D proteins of HPIV3 and BPIV3 the extension is longer (see e-Fig. 34.2). In general, the functions of the W, I, and D proteins are poorly understood. In the case of SeV, the W protein (like V, as noted above) was reported to downregulate viral genome replication in a reconstituted minireplicon system, an effect that was mediated by its P-related domain.^{71,151} The HPIV3 D protein was shown to accumulate in the nucleus of HPIV3-infected cells, but the significance of this is unclear.³⁹⁸

SH Protein

Among the PIVs, only PIV5 and AMPV6 encode SH proteins, which are 44 and 142 amino acids in length, respectively. MuV (Chapter 36) and all members of subfamily *Pneumovirinae* (Chapter 38) also encode SH proteins. In each case, SH is a transmembrane virion envelope protein with an externally oriented C-terminus. SH can be deleted without much effect on the magnitude of virus replication *in vitro*. However, deletion of SH from recombinant PIV5 resulted in increased cytopathology in cell culture due to increased apoptosis, although overall replication was not reduced, and the virus was attenuated *in vivo*.^{139,229} Further results indicated that infection with the Δ SH virus was associated with increased production of, and signaling by, tumor necrosis factor α , leading to the observed increase in apoptosis.²²⁹

Antigenic Composition and Determinants

Postinfection sera from animals and humans contain antibodies against most or all of the major PIV proteins. However, the HN and F proteins are the only antigens that have been shown to induce antibodies that neutralize infectivity, and they have been shown to be major independent protective antigens. *In vivo*, the parenteral administration of polyclonal or monoclonal antibodies specific to SeV HN or F mediated resistance to challenge with SeV.³⁰² Sera obtained from children following HPIV3 infection that contain antibodies specific to the HN and F proteins have been shown to have virus-neutralizing activity.¹⁸⁵ Infection of rodents with vaccinia virus recombinants expressing the HPIV3

HN or F glycoprotein, or immunization with purified HN and F glycoprotein, showed that either protein induced a high level of resistance to HPIV3 challenge, with HN being more protective than F.^{7,33,303,345}

The “internal” PIV proteins also induce a protective response. This was demonstrated in experiments in hamsters using a recombinant version of HPIV3 in which the HN and F surface antigen genes were replaced by those of HPIV1. This made it possible to compare the relative contributions of the “internal” proteins and the surface glycoproteins to protection.³⁶³ The HN and F proteins induced a high level of protection (in this case specific to HPIV1) that was long-lived. In contrast, the HPIV3-specific protection attributed to the internal proteins—which presumably was mediated by major histocompatibility class I-restricted, CD8+ cytotoxic T lymphocytes (CTLs)—was weaker and waned over a period of several months.³⁶³ This suggests that cellular immunity can contribute significantly to protection for a short period following infection, but is not effective in providing long-term protection.

Antibodies to HN can be measured by HI and neuraminidase-inhibition (NI) assays, which are based on the ability of the antibodies to block these activities of purified virions *in vitro*. Antibodies specific to the F protein can also be measured by inhibition of syncytium formation (fusion inhibition, FI) in cell culture, as well as by inhibition of hemolysis of erythrocytes by purified virions *in vitro*. However, since F activity also depends upon HN; as already noted, HN-specific antibodies also inhibit these activities.

The antigenic sites in the HN protein of HPIV3 were investigated by competitive-binding assays with pair-wise combinations of MAbs.³⁸⁴ Six antigenic sites were defined; five of the sites (A, B, D, E, and F) did not overlap, whereas site C overlapped sites A and B. Three of the sites (A, B, and C) reacted with MAbs that neutralize virus and inhibit hemagglutination.⁶¹ Amino acid residues important for the structures of the neutralization epitopes of HPIV3 HN were identified by sequence analysis of neutralization-resistant mutants selected with MAbs to sites A, B, or C (see Fig. 34.4).⁶⁰ Each of the mutants sustained a single amino acid substitution that in most cases was located in the C-terminal half of the molecule. Different MAbs directed to the same site selected amino acid sequence substitutions that were widely separated on the HN molecule, suggesting that these sites are formed by juxtaposition of distant regions in the folded structure. Consistent with this interpretation is the observation that boiling and reduction of the HN protein of HPIV3 or NDV markedly reduced reactivity with a panel of MAbs, and that neutralization epitopes could not be mimicked by synthetic peptides.¹⁴⁴ Many of the antigenic sites defined by the murine MAbs for HPIV3 HN (and F) are recognized by antibodies in postinfection human sera.³⁸⁶

The antigenic and functional organization of the HPIV3 F protein was elucidated by the same strategy. Competitive binding of a panel of HPIV3 F-specific MAbs identified seven nonoverlapping antigenic sites (A to G) and one site (AB) that bridged sites A and B.⁶¹ Neutralizing MAbs reacted with sites A, B, C, and AB, and at least some of the neutralizing MAbs represented by each site also inhibited fusion. The remaining sites reacted with MAbs that did not neutralize infectivity or inhibit fusion, and site A also reacted with a nonneutralizing MAb. Sequence analysis of neutralization-resistant mutants selected with individual MAbs showed that they contained single amino acid substitutions; those representing sites A or

B contained substitutions located in both the F₁ and F₂ subunits (Fig. 34.5).^{61,382} As was the case with the HN protein, this suggests that distant regions of the linear protein are folded into proximity to create antigenic sites. Consistent with this, F-specific MAbs that neutralize infectivity and inhibit fusion usually do not react efficiently with denatured F protein, such as in Western blots.

The primary antibody response to HPIV1, HPIV2, and HPIV3 is relatively specific to the infecting virus, consistent with their status as distinct serotypes.⁹² Although HPIV1, HPIV2, and HPIV3 each appear to be monotypic based on reactivity with postinfection sera, antigenic polymorphism within serotypes can be detected with MAbs. For example, analysis of 38 HPIV3 strains recovered over a 26-year interval in widely separated locations (United States and Australia) indicated that 6 of the 11 neutralization epitopes on HN, as well as 3 of 14 such epitopes on F, were completely conserved among all strains.^{60,61} The observed variation in HN and F neutralization epitopes did not seem to involve progressive accumulation of changes with time because variation detected in early isolates was not consistently conserved in later strains. Rather, it appears that the heterogeneity that exists results from random mutations that are not subject to strong immunologic selective pressure.⁶¹ Sequence analysis of HPIV1, HPIV2, and NDV has documented the apparent progressive accumulation of sequence differences, resulting in distinct “lineages,” but antigenic changes have been noncumulative and nonprogressive, and they do not correlate with the genetic lineages.^{147,301,316} Conversely, the detection of subgroups of APMV2, APMV3, and APMV6 that can be distinguished by reactivity with postinfection sera suggests that immune-driven divergent evolution can occur.^{214,352,402} The introduction of a vaccine against any of the HPIVs will provide an opportunity to evaluate the capability of circulating virus to accumulate antigenic differences compared to the vaccine strain.

Healthy adult humans tested for memory CD8⁺ CTL against HPIV1 demonstrated strong responses to HN, P, and N, a weak response to M, and an insignificant response to F in this particular subject group.⁷⁸ CTL lines that had been stimulated *in vitro* with HPIV1 showed high reactivity with the closely related SeV, and several cell lines recognized an N peptide that was conserved between HPIV1 and SeV. Remarkably, lower but clearly demonstrable reactivity also was detected against HPIV3 by the HPIV1-stimulated lines. Therefore, the human CTL response is directed against multiple HPIV proteins (as would be expected), and cross-reactivity between serotypes can occur.

Propagation and Assay of HPIVs in Cell Culture

The HPIVs grow well in primary simian or human kidney cell cultures, which allows efficient recovery of these viruses from clinical specimens. They also grow well and can be recovered in a number of established cell lines, including LLC-MK2 rhesus monkey kidney, Vero African green monkey kidney, and NCI-H292 human lung carcinoma cells.⁴¹ Growth of HPIV1 and HPIV4, but not HPIV2 or HPIV3, requires the addition of trypsin (1–5 µg/ml) to the medium for cleavage of the F₀ protein. Virus infection of cultured cells can be monitored by hemadsorption or by immunofluorescence staining. HPIV2 and HPIV3 produce a cytopathic effect that is characterized by syncytia formation, particularly in heteroploid cell lines, whereas

that of HPIV1 and HPIV4 is less. HPIV3 can readily be quantitated by plaque assay or by limiting dilution and direct observation of cytopathology, whereas plaque production or growth following limiting dilution by the other HPIVs usually is visualized by hemadsorption or immunostaining. Typical yields in tissue culture for HPIV1, HPIV2, and HPIV3 are 10⁷ to 10⁸ 50% tissue culture infectious dose (TCID₅₀) per milliliter of medium, whereas replication of HPIV4 is substantially less efficient.⁴¹

The ability of a PIV to replicate efficiently in a given cell culture depends in part on whether it can interfere with type I IFN production and signaling in that particular host. For example, SeV efficiently blocks IFN production and signaling in mouse cells and efficiently grows in those cells. In contrast, PIV5 does not efficiently antagonize the IFN system in murine cells, and growth is inefficient; however, efficient growth is achieved if IFN is depleted by adding IFN-specific antibodies to the medium or if the cells are from a genetically manipulated mouse that lacks the type I IFN receptor.⁸⁴ Typically, a virus can antagonize the IFN system in its native host but not necessarily in heterologous hosts.

The Nature of Cell Injury

The nature of cell injury *in vivo* is not fully understood and seems to involve different pathways for different PIVs. Some viruses, particularly PIV5, can cause a persistent, productive infection in primary cell culture that does not kill cells or shut off cellular RNA or protein synthesis.⁵⁷ In contrast, syncytia formation leading to cell death is a prominent feature of infection of monolayer cell cultures with HPIV2 or HPIV3. As noted, a number of viral products, including the C, V, and SH accessory proteins and the SeV trailer RNA, modulate and reduce cytopathology by inhibiting apoptosis and preventing activation of PKR that otherwise inhibits translation. In some situations, the persistence of PIV5 may also be related to its ability to form cytoplasmic bodies that sequester viral nucleocapsids and may provide for prolonged low-grade infection.⁴⁰

Recently, the characteristics of HPIV infection were studied in a culture system of primary human airway cells that are differentiated into a pseudostratified mucociliary epithelium that closely models the epithelium of the conducting airways (Fig. 34.6).⁴¹¹ HPIV3 infection was highly specific to ciliated cells on the apical surface of the tissue, and virus release occurred exclusively from the same face. Interestingly, there was no evidence of cell-to-cell fusion or spread to underlying cells, and the tissue remained intact over the 2-week duration of the experiment,⁴¹¹ in contrast to influenza A virus, which was rapidly cytopathic in this system.⁴¹² Therefore, HPIV3 is not inherently a highly cytotoxic virus. Similar observations have been made with HPIV1 and HPIV2 infections in this *in vitro* model,^{15,323} as well as with HRSV (Chapter 38).⁴¹² It may be that much of the cytopathology observed *in vivo* is the result of the host response to infected cells rather than direct viral damage. When the HPIV3-infected cultures were maintained over a course of 2 weeks, most of the infected cells were shed into the medium, possibly by an acceleration of the normal mechanism of cell shedding and replacement. In addition, there was a substantial increase in mucin-containing cells, which is consistent with the increased mucus production observed in infected individuals.

In the *in vitro* model of human airway epithelium, the lack of cell-to-cell fusion appeared to be a consequence of the

FIGURE 34.6. Infection of an *in vitro* model of human airway epithelium by HPIV3. Primary cultures of human airway epithelium, consisting of pseudostratified mucociliary tissue that closely resembles authentic airway epithelium, were infected with approximately 3 plaque-forming units (PFU) per cell of recombinant HPIV3 expressing green fluorescent protein (GFP) from an added gene and were viewed 48 hours postinfection. **A** and **B**: GFP expression in cultures that were infected on the **(A)** apical or **(B)** basolateral surface, viewed *en face* (i.e., from the top) by fluorescence microscopy at low magnification. **C** and **D**: Cross sectional images of infected cultures at higher magnification. **C**: Fluorescence microscopy reveals GFP-expressing parainfluenza virus 3 (PIV3)-infected cells, with counterstaining by antibodies against β -tubulin to identify cilia (*red*). **D**: Infected cells stained with hematoxylin and eosin, illustrating the lack of syncytia and cytopathic effects.⁴¹¹ Bar, 20 μ m.

tightly polarized nature of the apical cells: surface expression of the F glycoprotein was localized to the apical surface and probably was restricted from contact with neighboring cells. Therefore, the syncytium formation that is prominent in non-polarized monolayer cultures might not be significant in the airway epithelium. Whether it occurs in the alveolar epithelium is unknown. In humans, the pathology of fatal HPIV disease usually does not include giant-cell formation unless the patient has a severe defect in T-lymphocyte function^{82,171} or is profoundly immunosuppressed.³⁹⁵

Infection of HPIVs in Experimental Animals and Other Laboratory Hosts

Hamsters are readily infected by HPIV1, HPIV2, or HPIV3 and support moderate levels of virus replication. However, infection usually is asymptomatic, and pulmonary pathology is minimal or undetectable. Guinea pigs, cotton rats, and ferrets also undergo

a semipermissive silent infection with these viruses, but mice are poorly permissive. Chimpanzees and a variety of monkeys can be infected with HPIV1, HPIV2, and HPIV3, but only HPIV3 has been reported to cause symptomatic illness that sometimes occurs in both chimpanzees and African green monkeys.^{59,92} The absence of significant disease in most experimental animals is associated with limited virus replication.

Some strains of HPIV1, HPIV2, or HPIV3 replicate in the embryonated chicken egg, whereas others do not, and eggs are less reliable and sensitive for the isolation of virus from patients than are monkey kidney cells.

Genetics and Reverse Genetics

As is typical for RNA viruses, PIVs have a high rate of nucleotide misincorporation of approximately 10^{-3} to 10^{-4} . This provides the potential for rapid evolution and, indeed, PIVs readily “evolve” under selective pressure *in vitro*.¹³³ However,

these viruses appear to evolve very slowly in nature. For example, the HPIV3 F and HN glycoproteins have undergone little variation (1.5% to 2.4% amino acid sequence differences) since the first strain was recovered from humans.⁶¹ With NDV, sequence analysis of the F and HN genes from strains collected over a 50-year period identified what appeared to be the progressive accumulation of a small number of sequence changes, but these did not correlate with antigenic differences and overall the sequences remained highly conserved.^{316,373}

Like other paramyxoviruses, PIVs readily produce defective interfering (DI) particles when virus is passaged *in vitro* at high multiplicities of infection.³⁰⁴ DI genomes contain large deletions created by polymerase jumping during RNA replication. The polymerase can reinitiate further down the genome to produce an internally deleted molecule containing unaltered 3' and 5' ends, or, more commonly, can reinitiate on the nascent strand to produce a copy-back RNA in which the ends are exact complements. In either case, DI genomes lack most or all of the viral genes, are dependent on complementation by standard virus, and interfere with its replication. For this reason, care is taken to avoid high-multiplicity passage of PIVs. DI particles have been proposed to be a mechanism of down-regulating standard virus replication based on their effects in cell culture, but the significance of this for infections *in vivo* is unclear. Copy-back DI genomes of SeV have been shown to be highly effective inducers of type I IFN, and the presence of such DI particles in PIV vaccine preparations may increase immunogenicity due to the adjuvant effect of IFN.^{16,349} In addition, copy-back DI genomes typically have antigenomic promoters on both the positive and negative strands and are particularly active in expressing the anti-apoptotic trailer-RNA noted above, which may aid virus infection and viral persistence.

It is generally thought that recombination between co-infecting viruses to produce mosaic genomes containing segments from each parent is very rare for *Mononegavirales*.^{50,295,316} Early attempts to demonstrate the generation of a mosaic recombinant virus during mixed infections, such as with NDV, were unsuccessful.^{77,126,127} A mosaic virus has been produced experimentally only once for *Mononegavirales*, with HRSV.³⁴³ However, there have been reports of viral genomes with sequence discontinuities that may be indicative of RNA recombination.⁶³ Among the PIVs, this has been noted in particular for NDV, perhaps because the widespread use of live vaccines provides the potential for recombination with endemic wild strains.^{56,135,141,298} This evidence remains indirect, and at least some of the cases were found to be PCR artifacts rather than real mosaic genomes.³⁴¹ Recombination probably is a rare event that occurs mostly between closely related viruses, and there is no evidence that it is an important force in PIV evolution.^{50,63,316}

Complete infectious PIV can be produced entirely from cloned complementary DNA (cDNA) by the reverse genetics strategy that has been developed for *Mononegavirales*.^{93,138,267,285,325,337,351} This involves transfecting cells with plasmids that express an RNA copy of the genome or antigenome together with the N, P, and L proteins. These components assemble into a nucleocapsid that launches a productive infection. Reverse genetics provides a method to engineer predetermined changes into infectious virus for use in a variety of studies, including vaccine development.

A second type of reverse genetics system involves minireplicons, which are short cDNA-encoded versions of genomic or

antigenomic RNA. In some cases, the minireplicons are modeled after DI genomes; in other cases they resemble genomic RNA in which the viral genes have been replaced by one or more marker genes such as luciferase.^{94,365} When complemented by the appropriate mix of viral proteins supplied by co-transfected plasmids, the minireplicon is encapsidated and undergoes efficient RNA replication and transcription and packaging. A minireplicon system has advantages for detailed mutational analysis of *cis*-acting RNA signals or *trans*-acting viral proteins because of its smaller, simpler construction and because mutations that might have drastic effects on infectious virus can be studied in this transient system.

Natural Histories of the Animal PIVs

As noted, SeV was first detected in mice that had been inoculated with material from a fatal case of pediatric pneumonia, but the virus is recognized as a pathogen of rodents rather than humans.²⁶⁴ SeV replicates and causes disease in the respiratory tract of mice, and also readily infects hamsters, guinea pigs, and rats. SeV has been detected in mouse colonies worldwide, but is infrequently detected in wild mice, which makes its natural history somewhat unclear.^{101,281} In addition, SeV has been recovered from pigs experiencing outbreaks of influenza-like disease, but pigs are not thought to be a natural host.¹⁰¹ In experimental infections, SeV replicated in the respiratory tract of African green monkeys and chimpanzees with an efficiency similar to that of HPIV1, and thus may not have a substantial host range restriction in primates.³³⁵ This raises the possibility that SeV can initiate zoonotic infections in humans, which is one possible explanation for its original isolation from a human autopsy specimen. However, if this indeed ever occurred, it appears to be a rare event. The virus was well tolerated when administered experimentally to healthy adult humans,³³⁹ although it is not clear whether this reflects restriction by host range or by HPIV1-specific immunity present in most adults. SeV presently is being developed as a potential vaccine vector for human use,^{164,410} as a vector for gene therapy in the airway,¹²⁹ and as an oncolytic agent.¹⁷⁶

BPIV3 is a common cause of respiratory infections in cattle, and usually is associated with mild disease. However, it can promote secondary bacterial infection resulting in severe respiratory disease (shipping fever). Both inactivated and live attenuated vaccines against BPIV3 are available. BPIV3 is highly restricted in rhesus monkeys³³³ and in humans,¹²⁸ in which it has been evaluated as a potential live vaccine against HPIV3 (see Prevention and Control). The host range restriction of BPIV3 was investigated using reverse genetics to exchange each gene of HPIV3 with its counterpart from BPIV3. Evaluation of the resulting chimeras in rhesus monkeys showed that all of the BPIV3 genes contribute to the host range restriction, with N and P (the latter including all of the multiple ORFs) making the greatest contribution.³³³

PIV5 is a natural pathogen of dogs^{21,22} and causes acute self-limiting tracheobronchitis with the potential to progress to pneumonia, particularly since infection can promote opportunistic bacterial infection. In addition, PIV5 was recovered from a dog with posterior paralysis in 1978, and this isolate was neurotropic and caused acute encephalitis when inoculated intracerebrally in gnotobiotic puppies.¹⁷ Vaccination of puppies against PIV5 is routine. Although PIV5 was first isolated as a contaminant of primary rhesus monkey kidney cells, it does not appear to infect monkeys in the wild.¹⁵⁷ However, captive monkeys readily seroconvert, implying that they are

exposed to the virus during captivity, perhaps by human handlers. When inoculated intranasally into nonhuman primates, PIV5 was shed from the upper and lower respiratory tract for a week with mild or no illness. In some animals, the virus was reported to be isolated from the kidneys up to 113 days postinfection, although no viremia was detected.¹⁵⁷ PIV5 also has been isolated from the lungs of a stillborn piglet.¹⁴³

PIV5 has reportedly been isolated from a variety of human tissues, leading some researchers to suggest that the virus naturally infects humans and may establish persistent infections.^{51,120,121,157} PIV5 also has reportedly been detected in association with a number of human diseases ranging from the common cold to neurologic diseases (multiple sclerosis, subacute panencephalitis, and Creutzfeldt-Jakob disease). However, infection and possible persistence of PIV5 in humans remain to be clearly demonstrated, and the virus has not been clearly associated with any human disease.⁵¹ Detection of PIV5-specific antibodies in human populations is confounded by its antigenic relatedness to common human pathogens such as HPIV2 and MuV. In addition, the ability of PIV5 to readily contaminate cell cultures raises doubts about reports of its detection and possible association with various diseases. Therefore, the possible status of PIV5 as a common infectious agent in humans—either benign or pathogenic—remains unresolved but is generally considered unlikely. Comparison of partial genome sequences of PIV isolates from human, canine, simian, and porcine sources did not reveal any striking differences, and the isolates did not differ in the species specificity of their IFN antagonists.⁵¹ This suggests that these isolates represent a single viral species rather than a series of host-specific relatives. PIV5 is presently being investigated as a possible vaccine vector for human use,³⁷¹ although the unresolved issue of possible long-term infections in humans should be cause for caution.

Evidence of PIV infection in an unexpected host must be viewed critically. As noted, antigenic cross-reactivity between PIVs complicates serologic studies. The high prevalence of circulating PIVs in human and animal populations raises the possibility of contamination of tissue specimens and cell cultures, leading to false “isolations.” For example, antigens to HPIV1 and HPIV3—in addition to PIV5—were reported in a large fraction of bone marrow cell specimens,¹²⁰ indicating either that all three viruses persistently infect bone marrow cells (which seems unlikely), or that contamination had occurred. In addition, PIVs in general are highly infectious and sometimes can readily infect other species that are not necessarily natural hosts. An APMV2-like virus was isolated from cynomolgus monkeys with respiratory tract disease.²¹⁷ An APMV3-like virus was isolated from pigs in Israel.²³¹ Nonhuman primates are readily infected in captivity with HPIVs from their handlers. A paramyxovirus isolated from a wild Samango monkey was shown by sequence analysis to be HPIV3, and did not exhibit any evidence of divergence compared to a number of human isolates and thus likely was a virus of human rather than simian origin.²¹² HPIV3 was isolated from a pig with respiratory tract disease, and serologic studies provided evidence of infection on some farms.¹²⁵ More recently, analysis of PIV-like isolates from swine indicated that they were variants of BPIV3 that infected swine but did not become established in that host.²⁹⁷ Taken together, these incidents suggest that the PIVs, being highly prevalent and infectious viruses, sometimes can infect and cause disease in certain nonnatural hosts without becoming established.

As noted, SV41 is a relative of HPIV2 and PIV5 that was isolated from cynomolgus monkey kidney cell cultures. Its natural history remains unclear. When SV41 was inoculated intracerebrally into suckling mice, adult mice, hamsters, guinea pigs, 2-week-old chicks, and rhesus monkeys, it caused central nervous system disease signs in all of the animals and killed most of them.²⁵¹ Approximately 2% of tested human sera had antibodies that reacted with SV41, which was confirmed by immunoprecipitation of the SV41 HN protein by positive sera. This raises the possibility that the virus may sometimes infect humans.²⁷¹ The natural host(s) for SV41 remains unknown.

NDV (APMV1) is among the most important pathogens of poultry worldwide.³¹⁷ As noted, the many isolates or strains of NDV exhibit a broad spectrum of virulence. Vaccines against NDV are in widespread use, and North America, Australia, and New Zealand are relatively free of the disease.³¹⁷ Velogenic and mesogenic strains of NDV are classified by the Centers for Disease Control and Prevention (CDC) and the U.S. Department of Agriculture (USDA) as Select Agents—necessitating strict regulation of the possession and transfer of the virus—due to the potential risk for poultry farming. NDV infects more than 240 species of birds, with disease varying greatly depending on the virus strain and the host species. In addition, NDV can infect humans, particularly poultry farmers or laboratory workers working with the virus, but usually causes only mild conjunctivitis.³⁹ However, NDV was the apparent etiologic agent of fatal pneumonia in an adult who had been a recipient of a peripheral blood stem-cell transplant and as a consequence had increased susceptibility to infection.¹¹⁹ There are no reports of human-to-human infection. NDV can replicate in the respiratory tract of nonhuman primates, but is highly restricted.^{35,36} Lentogenic and mesogenic strains of NDV are being developed as vaccine vectors to express the protective antigens of other agricultural pathogens^{114,160,266,280} and human pathogens.^{35,36,86,87} In addition, NDV is being developed as a potential oncolytic agent.^{96,97,99,296,389}

Eight other serotypes (serotypes 2–9) of APMV have been identified based on antigenic differences measured by HI and NI assays,³¹⁷ and as noted there is new evidence for an additional, 10th serotype.²⁵⁰ Some serotypes exhibit limited cross-reaction and cross-protection, such as between serotypes 1 and 3. APMV serotypes 2 to 9 have been isolated worldwide from various wild and domesticated birds, although their natural histories are generally unknown. APMV serotypes 2, 3, 6, and 7 have been associated with mild disease in poultry, whereas the others have not been associated with poultry disease. There is serologic evidence in commercial poultry for all of the APMV serotypes except for 5 and 10, although this analysis may be complicated by cross-reactivity and the use of NDV vaccines.³⁹¹ As noted, complete genome sequences have been determined for one or more representatives of each APMV serotype.

PATHOGENESIS AND PATHOLOGY

The HPIVs replicate in epithelial cells that line the respiratory tract, causing rhinitis, pharyngitis, laryngitis, tracheobronchitis, bronchiolitis, and pneumonia (Table 34.5). Early during HPIV infection, the mucous membranes of the nose and throat are involved. Obstruction of the paranasal sinuses and eustachian tube may also occur and lead to sinusitis and otitis media. Many

^aInfection documented by virus isolation and/or a complement-fixing antibody response.

^bStudies performed at Children's Hospital National Medical Center from 1957 to 1976.^{194,195,260} Data were summarized by Murphy et al.²⁶⁰

^cTested from 1957 to 1968.

^dTested from 1968 to 1976.

HPIV, human parainfluenza virus; HRSV, human respiratory syncytial virus.

patients with mild disease may have limited involvement of the bronchi as well. In more extensive infections there is a tendency for HPIV1 and HPIV2 to involve the larynx and upper trachea, resulting in the croup syndrome; such infections may extend also to the lower trachea and bronchi, with accumulation of inspissated mucus and resultant atelectasis and pneumonia.²⁸³ When HPIV3 produces severe disease, infection of the small air passages is likely, with the development of bronchopneumonia, bronchiolitis, and/or bronchitis.^{283,397}

An intensive longitudinal study of infants and children in a semiclosed nursery indicated that 80% of individuals undergoing primary infection with HPIV3 developed a febrile illness; in one third of the illnesses, there was involvement of the lower respiratory tract, resulting in either pneumonia or bronchiolitis.⁴⁶ When infants and children were studied less intensively in a family setting, the estimate for lower respiratory tract involvement during primary HPIV3 infection was 13%.¹¹⁸ Longitudinal nursery studies also indicated that one half of initial HPIV1 infections and two thirds of initial HPIV2 infections produced a febrile illness.⁴⁶ Lower respiratory tract involvement also occurs commonly during primary HPIV1 infection; about 25% of primary infections produced bronchitis or pneumonia.¹¹⁷ Severe acute laryngotracheobronchitis (croup), which is the most dramatic and serious manifestation of initial HPIV infection, was noted in only 2% to 3% of primary HPIV1 or HPIV2 infections in longitudinal studies of healthy children,^{46,116} although HPIV1 and HPIV2 are the major etiologic agents detected among children who develop croup.

The magnitude of viral replication *in vivo* in the natural host appears to be a major factor in pathogenesis. For example, clinical trials of two candidate live-attenuated HPIV3 vaccines indicated that a virus that was highly restricted in replication was well-tolerated in young children, whereas a virus that was less restricted in replication produced fever and LRI in some vaccinees.^{19,184} Similar observations have been made with HRSV vaccines.¹⁸²

A possible role of the immune response in pathogenesis was suggested by the observation that infants and children who develop croup associated with HPIV infection produce local, virus-specific immunoglobulin E (IgE) antibodies earlier and

in larger amount than patients of comparable age with HPIV URI.³⁹⁶ In addition, histamine is detected in nasopharyngeal secretions of croup patients more often than in secretions from patients with URI caused by the same virus.³⁹⁶ Based on these observations, it was proposed that more rapid and increased production of HPIV-specific IgE antibodies mediates histamine release in the trachea and the subglottic region, which in turn produces the symptoms of croup.³⁹⁶ However, it is not clear whether a more pronounced virus-specific IgE response plays a role in pathogenesis of croup or whether it merely reflects more extensive production of viral antigens and consequent increased antibody response during severe disease. Measurement of proinflammatory cytokines in nasal washes obtained from children with HPIV infections demonstrated increased levels of interleukin 6 (IL-6), CC chemokine ligand (CCL)3, CCL4, CCL5, CXC chemokine ligand (CXCL)8, and CXCL9 compared to nasal washes from control subjects, and increased levels of CXCL8 in children with HPIV LRI compared to those with URI.⁹⁵ Cell-mediated immune responses to HPIV antigens, as well as HPIV-specific IgE antibody responses, have also been reported to be greater among infants with HPIV bronchiolitis than among infected infants who developed only URI.³⁹⁶ These observations have been interpreted as evidence for a role of immunologic factors in HPIV bronchiolitis, but the caveat cited before also applies. Infection of epithelial cells with HPIV2 was reported to increase adhesion of, and concomitant cell damage by, neutrophils, suggesting another potential factor in immune-mediated pathology.³⁷²

PIVs have been used in a number of animal models to study airway responsiveness to various stimuli following infection. In the guinea pig, which undergoes a brief, self-limited, and asymptomatic bronchiolitis after intratracheal inoculation of BPIV3, hyperresponsiveness to both histamine and a choline receptor agonist, arecoline, was seen from day 4 until day 16 after infection.¹⁰³ The effect lasted through the full recovery of the epithelium but was accompanied by airway hypercellularity and depletion of mucosal mast cells. Similar responses to PIV5 have been observed in beagle puppies.²²⁶

Older children or adolescents who had severe croup as infants or young children may exhibit bronchial hyperactivity

following exercise or inhalation of methylcholine.^{131,234} It is not known whether heightened airway reactivity is a preexisting condition that contributes to the pathogenesis of croup or whether inflammatory damage during croup produces a prolonged state of increased reactivity. Clearly, an enhanced IgE and histamine response would assume greater importance if preexisting heightened airway reactivity, especially in the trachea and subglottic region, played a role in pathogenesis of croup.

The susceptibility of an individual to severe disease probably is influenced by that individual's genetic background. Studies with HRSV indicate that genetic differences in IL-4, IL-8, and other aspects of host immunity may be associated with a greater frequency of severe disease (see Chapter 38).²⁵² The same may be true for the HPIVs.

Microscopic pathology is not well defined, as very few fatal cases of HPIV disease have been studied. Syncytium formation was observed in the lungs of two infants with severe immune deficiency who died of HPIV3 pneumonia; however, syncytium formation is not a feature of fatal HPIV disease occurring in immunocompetent individuals.^{3,82,90} As with HRSV bronchiolitis, the pathogenesis of HPIV3 bronchiolitis in young infants may involve mechanical events, such as mucus plugging and air trapping in the distal airways, but this has not been clearly defined.

The cleavage-activation of the F₀ precursor can be a major determinant of virulence for NDV, with the presence of a polybasic sequence containing the favored furin cleavage site (R-X-R/K-R↓) being associated with the ability to spread beyond the respiratory and enteric tracts and cause increased disease.²⁶² For example, natural outbreaks of virulent NDV in Australia in 1998 to 2000 appeared to arise from a low-virulence strain by mutation at the F₀ cleavage site that introduced a furin motif, R-R-Q-G-R↓L to R-R-S/Q-R-R↓F.¹²⁴ Serial passage of avirulent NDV strains in chicken eggs and brain resulted in the progressive mutation to a polybasic/furin cleavage site and the acquisition of a highly virulent phenotype.^{81,329} Mutation by reverse genetics of the cleavage site in avirulent NDV to be polybasic with a furin motif resulted in a dramatic increase in viral virulence.^{279,285,309} However, in this latter case, the engineered strains did not gain the full velogenic phenotype, suggesting that other factors contributed to the difference between the lentogenic and velogenic phenotypes. Other studies have found instances where the cleavage site sequence did not predict the virulence phenotype. For example, highly virulent NDV strains from China have been described with the nonfurin cleavage sequence G-R-Q-G-R↓L.³⁶² Conversely, some strains from Africa had cleavage sequences containing the furin motif (R-R-Q-K-R↓F) and yet were isolated from healthy chickens,³²⁸ and NDV strains from pigeons with a polybasic/furin cleavage site R-R-K-K-R↓F were avirulent.^{88a} Recent studies of the other APMV serotypes have provided additional examples of incongruity between the F₀ protein cleavage site sequence and viral virulence.³¹⁷ For example, APMV2 has a nonfurin cleavage sequence (D-K-P-A-S-R↓F) and is avirulent in chickens, and mutation of this site into a variety of polybasic/furin sequences resulted in substantially increased replication *in vitro* but did not increase the virulence of the virus in chickens.³⁵¹ Therefore, the presence of a furin motif at the cleavage site can be a major determinant of APMV virulence in some situations but not others. The presence of phenylalanine versus leucine or isoleucine as the first

residue of the F1 subunit also has been suggested to be associated with intracellular cleavage²⁵⁴ and pathogenesis,¹⁹¹ but there are many exceptions to this association, some of which include examples noted above.

SeV is another PIV that depends on secreted protease for cleavage of its F₀ protein. SeV is considered to be strictly pneumotropic in mice, and the basis for this phenotype was investigated using a mutant, F1-R, which had acquired the ability to cause systemic infection.^{277,367,368} Characterization of F1-R and a series of related mutants identified the following three acquired abilities that were necessary in combination for the pantropic phenotype: (a) the ability of F₀ to be cleaved intracellularly, due to mutations near the cleavage site; (b) the ability of the virus to bud from the basolateral surface in addition to the normal apical budding, due to mutations in M; and (c) the ability of the virus to cause depolymerization of microtubules, which also mapped to M.^{277,367} The acquisition of intracellular cleavability was sufficient to confer the pantropic phenotype if the virus was administered systemically, confirming the idea that intracellular cleavability confers the ability to replicate widely. The further requirement for basolateral budding provides for delivery of the virus into subepithelial tissues and into the blood, providing for escape from the respiratory tract. It is not yet understood how microtubule depolymerization is related to the pantropic phenotype.

It is not clear how directly one can extrapolate from these observations made with animal PIVs to the HPIVs. For example, it is tempting to speculate that the ability of the F₀ protein of HPIV3 to be cleaved intracellularly, in contrast to HPIV1, might explain the greater predilection of HPIV3 to cause pneumonia. This could be evaluated experimentally by altering F₀ cleavability in recombinant virus. It also is not clear whether other determinants, such as polarity of budding, are significant for the HPIVs. HPIV3 buds exclusively from the apical surface and generally is pneumotropic. However, it readily spreads beyond the respiratory tract under suitable conditions. This was demonstrated experimentally by studies in which immunosuppression of HPIV3-infected cotton rats resulted in dissemination of the virus and productive infection in other organs (G. A. Prince, B. R. Murphy, and R. M. Chanock, unpublished observations). HPIV3 viremia also has been reported during infection of untreated hamsters.¹⁷³ Similarly, in children with severe combined immunodeficiency disease, systemic, fatal infection with HPIV3 has occurred, with dissemination to the liver, myocardium, and cerebrospinal fluid.^{102,106} The rare isolation of HPIV3 from cerebrospinal fluid associated with aseptic meningitis in infants and children,⁶⁸ and a single case report of HPIV3 viremia in humans, also indicates that these viruses can (rarely) disseminate from the respiratory tract in immunocompetent individuals. Therefore, host immunity, rather than viral tropism, seems to be a major factor in restricting HPIV3 to the respiratory tract.

Other factors involved in the differences in virulence among the NDV strains have also been identified. Reciprocal swaps of the HN protein between a virulent and an avirulent strain showed that the HN of the latter was associated with reduced receptor recognition, reduced neuraminidase activity, and reduced virulence, indicating that HN can contribute to tissue tropism and virulence.¹⁶² However, in another study, swaps involving HN from a velogenic strain did not confer increased virulence,⁹⁸ suggesting that the contribution of HN

depends on the strain. Other studies identified contributions to strain-specific differences in virulence by the NDV N, P, V, L, and, to a lesser extent, M protein.^{4,89,310} A limited comparison of virulent and avirulent strains of NDV indicated that reduced virulence was associated with reduced viral RNA synthesis.²³⁸

IMMUNITY

PIV infections of experimental animals and adults induce potent systemic and local humoral and cellular responses. However, immune responses to HPIV infections in infants and very young children are qualitatively and quantitatively deficient. For example, young infants undergoing primary infection with wild-type HPIV produce local nasal IgA antibodies that neutralize virus infectivity poorly or not at all,⁴⁰⁴ and infants infected with live-attenuated HPIV3 vaccines exhibit reduced serum antibody responses to the HN glycoprotein compared to older infants and children.¹⁸⁰ This is likely the result of immunologic immaturity, which is most evident during the first 6 months of life,⁷⁰ and suppression of the humoral response to virus infection by maternally derived, virus-specific serum antibodies present in young infants.⁷⁰ The production of poorly neutralizing local antibodies and the poor serum antibody response in this young age group may partially explain why symptomatic reinfection (especially with HPIV3) occurs during early childhood.

The ability of serum neutralizing antibodies to confer resistance to pulmonary replication by PIVs has been well documented in experimental animals, where parenteral administration of polyclonal or monoclonal virus-neutralizing antibodies conferred a high level of resistance to virus replication in the lower respiratory tract and a lower level of resistance in the upper respiratory tract.^{278,303} Studies of HRSV have demonstrated that significant resistance in the respiratory tract requires high titers of serum antibodies (approximately 1:390 and 1:3,500 for 99% reduction of virus titer in the lungs and

nasal turbinates, respectively, of cotton rats),^{294,330} and this likely also is the case for HPIVs. High titers of serum antibodies are likely required because there is no specific mechanism for transporting serum IgG to the mucosal surface of the lumen of the respiratory tract.

In a longitudinal study of HPIV3 outbreaks in infants and young children residing in a semiclosed nursery, preexisting serum neutralizing antibodies correlated with resistance to infection and illness.⁴⁶ However, resistance associated with serum neutralizing antibodies was only partial. One third of infants and children with a high serum antibody level became infected. Although reinfection occurred, a partial effect of immunity from previous infection was indicated by a shorter period of virus shedding compared to that observed during primary infection. Moderate levels of serum antibody were not associated with complete protection against febrile illness, which occurred approximately 40% as often as during first infection. A somewhat greater reduction of LRI was observed during second infections with HPIV3 in a longitudinal family study.¹¹⁸

The protective effect of serum antibodies against the HPIVs is also suggested by the relative sparing of young infants—who possess serum IgG antibodies acquired passively from their mother—from HPIV infection and associated disease. For example, the risk of infection with HPIV3 during the first 4 months of life is inversely related, in the aggregate, to the level of neutralizing antibodies present in cord blood.¹¹⁸ However, the protective effect of passive immunity to HPIV3 appears to be less than that observed for HPIV1 and HPIV2, as some infants with a moderately high level of maternally derived serum antibodies become infected with HPIV3 and develop illness.¹¹⁸

Experimental HPIV1 and HPIV2 infection of adults possessing varying levels of local nasal secretory IgA neutralizing antibodies and relatively high levels of serum neutralizing antibodies indicated that resistance to infection and URI was mainly a function of mucosal antibodies.^{340,375} Adults respond to reinfection by developing an increase in local nasal secretory IgA antibodies that neutralize virus infectivity (Fig. 34.7).³⁴⁰ In

FIGURE 34.7. Experimental infection of adults with wild-type human parainfluenza virus 1 (HPIV1). Adult volunteers, all of whom had evidence of previous natural infection with HPIV1, were administered 10^5 median tissue culture infective doses (TCID₅₀) of HPIV1 by the intranasal route, and the indicated parameters were monitored.²⁶¹

addition, the efficacy of IgA in mediating resistance has been demonstrated in studies in experimental animals. IgA and IgG were equally effective in providing resistance to SeV challenge in mice when administered directly into the respiratory tract.²⁴⁶ However, in the natural situation, IgA has the advantage of being specifically transported through the epithelium to the surface of the lumen as well as being able to neutralize virus within infected epithelial cells.²⁴⁶

The role of CD4+ and CD8+ T cells in recovery from pulmonary SeV infection was demonstrated in mice, the putative natural host.^{155,186,187} Intranasal infection resulted in a rapid increase in pulmonary CD8+ CTLs, whose appearance coincided with the decrease in titer of pulmonary virus and resolution of infection.¹⁵⁵ However, possible participation of other effectors such as secretory or serum antibodies was not defined. Immunization of mice with a peptide bearing a major epitope for CD8+ CTLs induced a high level of resistance to a short-term virus challenge.¹⁸⁷ Mice that had a mutant nonresponder class I restriction element failed to develop a virus-specific CD8+ CTL response upon infection, whereas serum antibody, delayed-type hypersensitivity, and natural killer (NK) cell responses were unimpaired. These mice cleared infection, but the LD₅₀ of SeV in these animals was 10-fold lower than that for wild-type congenic mice. In a situation in which infection was not lethal, removal of CD8+ cells, either through antibody depletion or disruption of the β 2-microglobulin gene, resulted in delayed viral clearance and 20% mortality.¹⁵⁵ In comparison, antibody-mediated depletion of CD4+ cells, which inhibited antibody production but did not affect the CD8+ CTL response, delayed viral clearance only marginally with no mortality. Removal of both subsets resulted in a failure to clear the virus and 100% mortality.¹⁵⁵ Pulmonary virus-specific CD8+ cells exhibited efficient cell-killing activity *in vitro*, suggesting that this is a likely effector function *in vivo*. CD4+ cells isolated from normal SeV-infected mice did not have significant *in vitro* cell-killing activity, nor did they seem to have a critical role in promoting the CD8+ response.¹⁵⁵ It seems likely that the major antiviral activity of CD4+ cells was to provide T-cell help for antibody-producing B cells.^{155,186}

The importance of virus-specific CD4+ and CD8+ T cells in recovery from HPIV infection has not been formally established. However, as already noted, immunization of hamsters with a recombinant chimeric HPIV3–HPIV1 virus containing the HN and F from HPIV1 and internal protein genes from HPIV3 afforded short-lived protection against HPIV3, presumably involving cell-mediated immunity.³⁶³ The importance of cell-mediated immunity in recovery from HPIV infections is also suggested by the experience of immunodeficient individuals (see Clinical Features).

Evaluation of the role of innate immunity in PIV infections has been limited mostly to identifying the mechanisms by which PIVs interfere with the induction of and signaling by IFN- α/β , as has already been described. As noted, these IFN-antagonist mechanisms are important for efficient infection, and the deletion of the viral proteins involved can be severely attenuating. However, IFN production and action usually are not completely blocked by these viral mechanisms and likely contribute to host defense. A significant proportion (30%) of young patients with HPIV1 infection develop a detectable IFN response (geometric mean titer of 23.5 units) during the acute stage of illness.¹³² This frequency is somewhat less than that

observed during influenza A virus infection of children (55%) but is decidedly greater than that observed during HRSV infection of infancy and childhood (4%).

In summary, innate immunity, antibodies, and cellular effectors such as CTLs play important independent roles in restricting and clearing an infection. With regard to virus-specific immunologic determinants that confer resistance against re-infection, local IgA plays a key role, but this protective effect can be relatively short-lived, especially following primary infection. Cellular immunity also confers short-lived resistance to reinfection. These short-lived effectors might be important in restricting reinfection during an ongoing epidemic season. Serum antibodies provide long-term protection that is more effective in the lower versus upper respiratory tract. Serum antibodies probably play the major role in resistance to lower respiratory tract infection observed in older children, adolescents and adults. Long-term resistance in the upper respiratory tract is less complete, and reinfection of the upper respiratory tract can occur throughout life. It also should be noted that the immunologic determinants of clearance and protection in the young infant, for whom severe PIV disease is most common, are not well understood.

EPIDEMIOLOGY

Morbidity, Mortality, Age

HPIV1, HPIV2, and HPIV3 have a worldwide distribution and cause acute respiratory illness in individuals of all ages, with the greatest impact in infants and young children. Historically, HPIV4 has been isolated less frequently, likely due in part to the greater difficulty of recovering this serotype in cell culture. However, serologic studies and recent studies using reverse transcription–polymerase chain reaction (RT-PCR) suggest that HPIV4 also is a ubiquitous pathogen that can infect and cause disease in both children and adults.^{100,137,306} Each of the four HPIV serotypes has been recovered more often from patients with respiratory diseases than from healthy individuals,^{45,46–47,193,282} and each has produced upper respiratory tract infection and illness when administered to adult volunteers.^{177,375,378,379}

HPIV infection generally occurs early in life. Serologic surveys indicate that at least 60% of children have been infected with HPIV3 by 2 years of age and that approximately 80% have been infected by 4 years of age.^{282,283} A longitudinal study of 121 infants and young children indicated that the incidence of HPIV3 infection was approximately 67 per 100 per year during the first 2 years of life.¹¹⁸ Infection with HPIV1 or HPIV2 generally occurs somewhat later, but by 5 years of age a majority of children have been infected with HPIV2, and more than 75% have been infected with HPIV1.^{282,283} Pneumonia and bronchiolitis associated with HPIV3 infection typically occur during the first 6 months of life, whereas severe illness caused by HPIV1 or 2 is rare in early infancy.^{45,46,115} The incidence of croup, which is principally caused by HPIV1 and HPIV2, peaks between 1 and 2 years of age, but croup remains an important cause of LRI in children up to 6 years of age.^{145,197}

In infants and young children, disease caused by HPIV1, HPIV2, and HPIV3 can range from mild URI to life-threatening LRI. Table 34.5 shows typical data on the frequency of detection of various respiratory viruses in pediatric inpatients with respiratory tract disease, as well as the association between

these viruses and various clinical manifestations, from a prospective study from 1957 to 1976 in Washington DC.²⁶⁰ In this study, the percentage of pediatric hospitalizations attributable to HPIV1, HPIV2, and HPIV3 was 6.0, 3.2, and 11.5, respectively, compared to 23.3 for HRSV. It should be noted that these data are more than 35 years old, and the now-routine treatment of croup with steroids in outpatient and emergency room settings has markedly reduced hospitalizations for this illness, which is mainly caused by HPIV1 and HPIV2. A more recent study in the United States estimated that HPIV1, HPIV2, and HPIV3 were responsible in aggregate for 6.8% of all hospitalizations for fever and/or acute respiratory illnesses in children younger than 5 years of age, with the different serotypes being responsible for 38%, 12%, and 50% of the HPIV-associated cases, respectively.³⁹³ Therefore, HPIV1, HPIV2, and HPIV3 differ in their contribution to severe respiratory tract disease, with HPIV3 having the greatest impact. One retrospective review of the pediatric medical burden of HPIV3 in the United States estimated that, in children younger than 5 years of age, the virus was responsible yearly for up to 3.24 million cases of medically attended acute respiratory illness (MAARI; rate of 16.9% in that age cohort), 1.08 million cases of LRI (rate of 5.6%), and 29,000 hospitalizations (rate of 0.15%),²²³ although a limitation of this study was that rates of outpatient MAARI were extrapolated from rates of LRI. The rate of medically attended HPIV3 disease and LRI was more than threefold greater for those younger than 2 years of age compared to 2 to 5 years of age, and the rate of HPIV3 hospitalization was nearly fivefold greater for those younger than 1 year of age compared to 2 to 5 years of age.

In addition, Table 34.5 illustrates that HPIV1, HPIV2, and HPIV3 each has diversity in its clinical manifestations, with considerable overlap between viruses. However, there are differences in the frequency of association of specific HPIVs with specific illnesses. HPIV1 is the principal cause of croup in children: studies that utilized virus isolation for diagnosis indicate that HPIV1, HPIV2, and HPIV3 are associated with approximately 50% to 75% of cases of croup,^{83,197,305} with HPIV1 responsible for 40% to 65% of all cases.⁸³ In contrast, the principal serious illnesses caused by HPIV3 are pneumonia and bronchiolitis.^{45,47,49,83,282} HPIV2 closely resembles HPIV1 in clinical manifestations, but severe illness occurs less frequently.

Pediatric illness associated with HPIV4 is generally thought to be less severe than with the other HPIV serotypes, although the virus has been found in association with a broad spectrum of clinical manifestations including severe LRI.^{100,306,338} HPIV4 may account for approximately 10% of pediatric HPIV infections, a prevalence that is less than that of HPIV1 and HPIV3 and may be similar to that of HPIV2.^{100,306,338}

The HPIVs commonly reinfect children and adults. However, illness in healthy older children and adults usually is limited to URI; LRI associated with re-infection is rare, although this does occur on occasion and can result in hospitalization.²⁴³ Although the frequency of reinfection is not known, it is probable that most individuals have repeated experience with HPIV1, HPIV2, and HPIV3. In a series of three outbreaks of HPIV3 infection in a semiclosed nursery population, it was observed that 17% of the children infected during one outbreak were reinfected during a subsequent outbreak, although the interval between the first and last outbreaks was only 9 months.⁴⁶ Reinfection by HPIV3 of preschool children living at home

also occurs with high frequency, and usually is associated with a lower incidence and severity of disease compared to primary infection.¹¹⁸ HPIV4 also has been detected in adults with medically attended influenza-like illness.¹³⁷

HPIVs are readily spread in the family setting. In a longitudinal study of families with young children, the overall rate of HPIV infection as estimated by serology (HI and complement-fixation assays) was 44.4 infections per 100 person-years.¹⁰⁴ The rate of HPIV infection varied from 59% for children 2 to 5 years of age to 40% for adults. Spread of virus within infected families was extensive, as indicated by serologic studies: following infection of an index case, 64% of family members developed a serum HI antibody response. HPIVs are typically introduced into the family by preschool children.¹⁰⁴

Nosocomial HPIV infections are particularly problematic in hospitalized children and in immunocompromised patients.²⁵⁹ Nucleic acid sequence analysis has been used to analyze hospital outbreaks, and it is clear that, although outbreaks caused by a single genotypically uniform strain can occur, much of the problem is due to sporadic spread of multiple strains within the hospital or community.¹⁸¹ Infection in hospital staff can occur and may be a factor in spread.³³¹ Transmission may also occur among immunocompromised patients in an outpatient department.²⁶⁹

Mortality due to the HPIVs has not been carefully studied but is thought to be uncommon in otherwise healthy individuals (see Clinical Features in this chapter for information on immunodeficient individuals). Although estimates of the fatality rates for the HPIVs are not available, the aggregate rate is thought to be substantially less than for HRSV, another common viral cause of severe pediatric respiratory tract disease (Chapter 38). In one study in Brazil, immunohistochemical analysis of necropsy samples from fatal respiratory infections (200 subjects, aged 1 month to 14 years, median age 7 months) detected HPIV1, HPIV2, and HPIV3; HRSV; and influenza A in 6.5, 8.0, 15.5, 21, and 10.5 percent of cases, with many cases having more than one virus.⁸⁸ Another report described a fatal case of HPIV1-confirmed laryngotracheitis, with no evidence of bacterial superinfection, in a 15-month-old toddler.²³⁶ Therefore, infection with the HPIVs can be fatal, although this is uncommon.

The seasonality of HPIV infections has been most clearly defined in temperate climates, principally in the United States. From 1957 to 1961, HPIV1 appeared to be endemic; infection occurred sporadically and without a definite seasonal pattern.^{45,46} Beginning in 1962, a different pattern developed, in which sharp outbreaks of HPIV1 occurred every 2 years in the autumn of even-numbered years. In contrast, HPIV2 caused outbreaks in the autumn of odd-numbered years.^{46,116} At present, HPIV1 epidemics occur during the fall of odd-numbered years. HPIV2 epidemics occur annually in the fall,¹⁶⁹ but infection with HPIV2 can also occur at other times.³⁹⁴ For many years, HPIV3 exhibited an endemic pattern, with infection occurring in all seasons of the year. Within the last 15 years, there has been a shift toward yearly epidemics of HPIV3 infection in the spring and summer. In North America, the seasonality of croup primarily mirrors the seasonality of HPIV1, with large peaks occurring in odd-numbered years in the fall^{83,244,327} and smaller peaks occurring in the winter, reflecting influenza and HRSV as additional causes of the syndrome.

One of the hallmarks of the HPIVs is that they persist in the population without undergoing significant antigenic

change. This persistence is likely the result of reinfection and subclinical infection in older children and adults throughout life. HPIV infections induce potent systemic and local humoral and cellular responses (except in young infants) that are thought to completely resolve the acute infection. Serum antibody responses are durable, but local respiratory tract IgA and cellular responses can be more transient, which may contribute to the ease of reinfection. In addition, reinfection is facilitated by the ability of the HPIVs to block the host IFN response. A number of PIVs readily establish persistent infection in cell culture^{57,113,257} raising the possibility that persistent infection might be another mechanism for maintaining virus in the population. However, although prolonged infection by HPIVs can occur in immunocompromised individuals, evidence for persistence of HPIVs in healthy hosts is lacking.

Spread and Infectivity

Transmission of HPIVs is by direct person-to-person contact or by large-droplet spread; however, the viruses do not persist long in the environment. These viruses spread rapidly following introduction into day care, family, and institutional settings. There is evidence from studies in adult volunteers that the infectious dose of HPIV1 is small. For example, in one study, two thirds of adults who possessed a moderately high level of preexisting serum-neutralizing antibodies became infected and developed a “common cold-like” illness following intranasal instillation of 80 TCID₅₀ of HPIV1.³⁴⁰ In addition, reinfected individuals appear to be infectious. HPIV3 appears to be the most efficient of the HPIVs in its ability to spread from person to person. HPIV3 generally infects all susceptible individuals in a semiclosed population (such as a nursery) in a relatively short time.⁴⁶ In contrast, HPIV1 and HPIV2 appear to be less effective in this regard, infecting 40% to 69% of susceptible individuals in semiclosed populations.⁴⁶ During experimental infection of adult volunteers, the interval between administration of HPIV1, HPIV2, or HPIV3 and onset of upper respiratory tract symptoms ranges from 3 to 6 days (see Fig. 34.7).^{177,340,378,379} The incubation period in pediatric infections has not been defined; however, in several institutional outbreaks of HPIV3 infection, the interval between exposure and the onset of virus shedding was 2 to 4 days.⁴⁶

The interval during which an individual infected with an HPIV can infect another person is not known. Longitudinal studies indicate that HPIV3 is usually shed from the oropharynx for 3 to 10 days (median of 8 days) during primary infection, whereas during reinfection the virus is detected during a shorter interval.⁴⁶ On occasion, infants and young children may shed HPIV3 during primary infection for as long as 3 to 4 weeks.¹⁰⁵ Prolonged shedding of HPIV3 has also been observed occasionally in adults with underlying chronic lower respiratory tract disease.¹³⁰ It is not clear whether chronic damage to the respiratory tract is responsible for this unusual manifestation of adult reinfection.

CLINICAL FEATURES

Most primary infections with the HPIVs result in respiratory illness. In children, the most common type of illness consists of rhinitis, pharyngitis, cough, and hoarseness, usually with fever.^{282,283} The cough may be croupy, but respiratory distress

is not present. Approximately three fourths of such ill children have a temperature above 100°F; fever usually lasts 2 to 3 days. Coarse breath sounds, rhonchi, erythema of the pharyngeal mucous membranes, and rhinitis are the characteristic physical findings. Cervical adenopathy is uncommon.²⁸³ Otitis media occurs frequently in HPIV infections, and virus can be detected in the middle ear fluids of patients with otitis media.¹⁴²

When acute laryngotracheobronchitis (LTB; croup) develops, the initial symptoms of rhinitis, pharyngitis, fever, and cough progress. After several days, the cough worsens and becomes brassy, “seal-like,” or barking, and stridor ensues. The illness typically varies in intensity, with the worst symptoms frequently observed in the evening and at night. Most children recover after 48 to 72 hours. In some children, however, air hunger develops, with cyanosis, sternal and intercostal retractions, and progressive airway obstruction. The anteroposterior (AP) radiograph of the neck (which should be obtained under carefully controlled medical supervision, if at all) shows glottic and subglottic narrowing (the “steeple sign”) and differentiates this disease from epiglottitis.

When bronchiolitis or pneumonia develops, fever persists and the cough progresses and becomes somewhat productive. It is accompanied by wheezing, tachypnea, retractions, and, in severe cases, cyanosis. The chest radiograph shows interstitial or perihilar infiltrates and air trapping. In some patients, a combined bronchopneumonia–croup syndrome occurs. There are also case reports of children who have developed severe pulmonary disease resembling the adult respiratory distress syndrome following HPIV infection.¹⁵⁴

HPIVs may cause prolonged and severe infections in patients with congenital and acquired immunodeficiencies, including those with severe combined immunodeficiency and those who have undergone hematopoietic stem cell transplantation (HSCT) or lung transplantation. In these patients, HPIV3 is the most frequently isolated serotype. In one large study of HSCT recipients, HPIV infection was documented in 7.1% of subjects: all four serotypes were detected, but HPIV3 accounted for 90% of the isolates.²⁶⁹ Of the HPIV3 cases, 24% developed pneumonia, and 35% of those died within 30 days. Steroid use was a risk factor for development of pneumonia. Co-pathogens were isolated from 53% of those with pneumonia and increased the risk of mortality.²⁶⁸ HPIV3 also causes LRI in lung transplant recipients and has reported associations with both acute allograft rejection and later development of bronchiolitis obliterans, an often fatal complication.³⁹⁰ In wealthy countries, prior infection with human immunodeficiency virus (HIV) does not appear to increase the morbidity and mortality associated with HPIV infection in children, although prolonged viral excretion has been reported.¹⁹⁶ In resource-limited countries, HPIVs have been reported to be associated with greater morbidity and mortality in HIV-infected than HIV-noninfected children, although the contribution of other illnesses cannot be excluded.²³⁹

DIAGNOSIS

Differential

In croup, other viral causes must be considered. Influenza A viruses (particularly H3N2 viruses) cause up to one third of croup cases (Table 34.5), but these are usually confined to epidemic periods. HRSV also occasionally causes croup. In

resource-limited settings, measles virus may also produce severe laryngeal inflammation. In regions where *Haemophilus influenzae* type B (HiB) vaccine is not used, epiglottitis becomes the most important differential diagnosis, although this disease is becoming increasingly rare with the global use of HiB vaccines. In contrast to croup, epiglottitis is usually of sudden onset, without a prodrome of rhinitis, hoarseness, or cough, and is accompanied by high fever, leukocytosis, a “toxic” appearance, and drooling. The AP radiograph of the neck is characteristic, as is the cherry-red enlargement of the epiglottis, which should be examined only as part of the intubation procedure or when preparations for nasotracheal intubation have been made. Another bacterial infection that must be differentiated from viral croup is bacterial tracheitis. This disease is usually caused by *Staphylococcus aureus* and may be a complication of viral croup rather than a primary bacterial infection. Intubation for bacterial tracheitis is frequently necessary, as well as antistaphylococcal antibiotic therapy. In bronchiolitis or pneumonia of infancy, other viruses (particularly HRSV and HMPV) and *Chlamydia trachomatis* are the most frequent etiologic agents to be considered.

Laboratory

Definitive diagnosis of HPIV infection requires viral isolation by conventional methods or spin-enhanced culture,²²⁴ identification of viral antigens in respiratory tract secretions by immunofluorescence, or detection of viral RNA in nasal secretions by reverse transcription followed by RT-PCR. For viral culture or immunofluorescence, specimens are best collected by nasal aspirate or nasal wash, but nose and throat swabs appear to be adequate for RT-PCR. To enhance recovery by culture, specimens should be transported to the lab on wet ice or “snap” frozen on dry ice and stored at -80°C. Increasingly, RT-PCR is being used as the diagnostic method of choice in both pediatric and adult populations because the sensitivity of these assays allows detection of even small quantities of virus (adults typically shed less virus than children). RT-PCR can be used in multiplex formats capable of detecting multiple pathogens, and several such assays are currently available. Immuno-compromised subjects may shed HPIVs for prolonged periods, which may make it difficult to correlate detection with specific disease states.

PREVENTION AND CONTROL

Treatment

Symptomatic treatment of croup usually includes humidification of air by ultrasonic nebulizer. Nebulized or systemic corticosteroids have been shown to decrease the frequency of intubation and hospitalization in moderate to severe croup.^{11,174} A single dose of oral dexamethasone in children with mild croup has been shown to shorten the duration of symptoms, improve patient sleep, and decrease parental stress.²⁵ Treatment with nebulized epinephrine is usually reserved for patients in severe respiratory distress.²⁵ Steroids act to reduce inflammation, whereas epinephrine relieves airway constriction through relaxation of smooth muscles.

Specific antiviral treatment is not available. The nucleoside analog ribavirin exhibits *in vitro* activity against the HPIVs, but is not recommended for use in otherwise healthy individuals

because its effectiveness is unclear; the same is true for HRSV. Ribavirin does find use in the treatment of HRSV and HPIV infections in HSCT recipients, although its effectiveness in this setting also is unclear.^{42,268} A number of potential inhibitors of the HPIVs that target various steps in the replicative cycle are in preclinical development. The neuraminidase inhibitor 4-GU-DANA (zanamivir) that was developed as an antiviral drug for influenza virus inhibits HPIV3 neuraminidase activity. However, it also interferes with HN binding to the cellular receptor and has the undesired effect of promoting HPIV3 release, which makes it unsuitable for therapy of HPIV infections.^{255,291} Using the crystal structure of NDV as a guide, neuraminidase inhibitors BCX 2798 and 2855 were developed and shown to be active in inhibiting HPIV1 in cell culture, and were effective in prophylaxis and treatment in mice against a recombinant SeV in which the SeV HN gene had been replaced with that of HPIV1.^{6,392} Another strategy has been to use recombinant sialidase to enzymatically remove sialic acid receptor molecules from target cells to block infection by HPIVs and influenza virus: this strategy has been shown to inhibit infection by HPIVs in cell culture and in cotton rats.²⁵⁸ Structure-based “virtual screening” for compounds predicted to interact with the active sites on the HPIV3 HN protein identified a small molecule that interacts with the HN protein and triggers premature activation of the F protein, with the result that entry is blocked.²⁵⁸ Fusion is driven by interaction between heptad repeats in the F protein (see Chapter 33), and synthetic peptides derived from these repeats have been shown to block this interaction and inhibit HPIV3 infection *in vitro*.²⁹³ This strategy is based on earlier work with HIV that resulted in the HIV fusion inhibitor enfuvirtide presently in use in anti-HIV therapy. The addition of cholesterol to HIV or HPIV3 peptides targeted them to the membrane and increased their antiviral activity.²⁹³ A novel small molecule LJ001 was recently described that intercalates into viral membrane and irreversibly blocks virus–cell fusion, and is active against a wide array of enveloped viruses including PIVs.³⁹⁹ Small molecules that inhibit HPIV3 transcription in cell culture have recently been described.²⁴² In addition, small interfering RNA (siRNA) targeting the HPIV3 N gene was reported to have antiviral activity in cell culture and in mice (with the caveat that HPIV3 replicates poorly in mice)²³; a similar strategy against HRSV has been shown to reduce virus infection and replication in clinical studies (Chapter 38). Recently, DAS 181, a recombinant sialidase containing the catalytic domain of *Actinomyces viscosus*, has been shown to have *in vitro* activity against all of the human PIVs²⁵⁸ and has been associated with viral clearance and clinical improvement when delivered via inhalation to stem cell or lung transplant patients with HPIV3 LRI.^{52a,91a,131a} Clinical evaluation of DAS181 is ongoing.

Vaccines

The primary need for HPIV vaccines is in the pediatric population, with the need being greatest for HPIV3 followed by HPIV1 and HPIV2. Given the epidemiology of the viruses, immunization against HPIV3 should begin by the second month of life (ideally given in combination with an HRSV vaccine), whereas immunization against HPIV1 and HPIV2 could begin in late infancy or early childhood. A major obstacle to developing pediatric vaccines is that antibody responses to live respiratory viral vaccines are frequently limited in infants at or below 6 months of age^{70,109} (see Immunity, above).

In early work, inactivated vaccines prepared with virus from infected embryonated eggs or primary monkey kidney cell culture were developed for HPIV1, HPIV2, and HPIV3 and shown to be immunogenic in children, as indicated by the development of serum HI and neutralizing antibodies. Unfortunately, parenteral administration of these vaccines failed to induce resistance to HPIV disease.^{55,107} Effective immunization against HPIV disease using a killed virus vaccine has not been demonstrated and is not an active area of research.

Subunit vaccines have also been evaluated, namely, preparations of the HPIV3 HN and F glycoproteins isolated from purified HPIV3 or from insect cells infected with recombinant baculoviruses expressing the HN or F protein or a chimeric form of HN and F encoded by an engineered cDNA.^{7,225,302,383} Parenteral immunization of cotton rats with these viral glycoproteins induced satisfactory levels of neutralizing, HI, and FI antibodies, and the immunized animals were highly resistant to intranasal challenge with HPIV3. In addition, intranasal administration of the purified glycoproteins was effective in inducing a local IgA response.³⁰³ However, none of these strategies has been validated in nonhuman primates or in clinical trials, which pose a more stringent test of vaccine efficacy, since HPIVs do not replicate efficiently in rodents and thus are readily restricted.

A major focus of current research is the development of live-attenuated intranasal vaccines for HPIV1, HPIV2 and HPIV3, either using attenuated versions of the native human HPIVs, or by using related nonhuman PIVs as vectors to express HPIV HN and F glycoproteins. Information about specific experimental vaccines is detailed below. Importantly, live attenuated respiratory viruses administered intranasally are infectious and moderately immunogenic even in the presence of maternal serum antibodies.⁴⁰⁰ Furthermore, these intranasally administered vaccines induce both local and systemic immunity.

HPIV3 Vaccines

Two biologically derived HPIV3 experimental vaccines that have been evaluated in clinical trials have served as prototypes for the development of live-attenuated HPIV3 vaccines. HPIV3 cp45 (cp45) was derived from the JS wild-type strain of HPIV3 by 45 passages in primary African green monkey kidney cells at low temperatures.¹⁸ This cp45 mutant exhibited three interesting properties: (a) cold adaptation (*ca*) (i.e., an ability to replicate efficiently at 20°C, a temperature restrictive for wild-type PIV3); (b) temperature sensitivity (*ts*) (i.e., a decreased ability to produce plaques at the high end of the normal temperature range); and (c) reduction in the level of replication (“attenuation” or *att*) in hamsters, monkeys, and humans.¹³³ The cp45 virus contains 20 point mutations that differentiate it from the JS wild-type strain, 10 of which are silent, without a change in amino acid sequence. Of the remaining 10 mutations, the ones associated with attenuation involve amino acid substitutions in the C, F, HN, and L proteins, with the L mutations playing the major role.^{332,334} The second candidate is BPIV3, which is naturally attenuated in humans, as already noted.⁶⁰ BPIV3 and HPIV3 are 25% related antigenically by cross-neutralization assays, which would reduce the effectiveness of BPIV3-specific immunity in restricting HPIV3. Both cp45 and BPIV3 have been evaluated in phase I and phase II trials in adults, HPIV3 seropositive children, HPIV3 seronegative children, and infants as young

as 1 month (cp45) or 2 months (BPIV3) of age. Both candidates were over-attenuated in adults and in seropositive children but were highly infectious in seronegative children and infants.^{20,59,178,183,184} There were no significant differences in the incidence of respiratory or febrile illnesses among seronegative vaccinees and placebo recipients, suggesting that the vaccines were well tolerated. Otitis media occurred more frequently among seronegative children vaccinated with HPIV3 cp45 in phase I trials than among placebo recipients, but this was not observed in infants vaccinated with HPIV3 cp45, or in phase II trials of HPIV3 cp45 in seronegative children. A recombinant form of the cp45 vaccine, designated rcp45, has been recently developed. rcp45 has the advantage of having a short, well-defined passage history using qualified cells and reagents. rcp45 was recently assessed in phase I and II trials in HPIV3-naïve children to determine the optimal dosage and dosing interval (clinicaltrials.gov NCT01021397, NCT01254175, and NCT01150799), and has been found to be comparable to the biologically derived cp45 vaccine with respect to tolerability, infectivity, and immunogenicity.¹⁷⁹ and unpublished observations

Although both HPIV3 cp45 and BPIV3 elicited HI antibody responses against HPIV3 in most vaccinated seronegative children, the magnitude of the HPIV3-specific response was lower in children who received BPIV3, consistent with the antigenic differences between BPIV3 and HPIV3.⁶⁰ For this reason, recombinant bovine/human PIV3 candidate vaccines containing the HPIV3 HN and F genes and one or more BPIV3 internal genes have been developed by reverse genetics (see below). These viruses were constructed either through replacement of the HN and F genes of BPIV3 with their counterparts from HPIV3³²⁵ or through replacement of individual “internal” protein genes (e.g., N or P genes) of HPIV3 with their counterparts from BPIV3. Two of these vaccines, rHPIV3-N_B (consisting of HPIV3 in which the N gene was replaced with its BPIV3 counterpart) and rB/HPIV3 (consisting of BPIV3 in which the F and HN genes were replaced with their HPIV3 counterparts), have recently been evaluated in phase I clinical trials (clinicaltrials.gov NCT00366782). Each candidate was highly attenuated in adults and seropositive children, but was infectious and immunogenic in seronegative children. An additional candidate, a chimeric vaccine designated MEDI-534, is a version of rB/HPIV3 that also expresses the HRSV F protein from an added gene placed between the N and P genes. This strategy thus provides a bivalent vaccine virus against HPIV3 and HRSV. MEDI-534 has been evaluated in a phase I trial in HRSV and HPIV3 doubly seronegative children ages 6 to 23 months (clinicaltrials.gov NCT00493285). Preliminary data from this trial indicate that all children who received the highest dose of vaccine (10⁶ TCID₅₀) were infected with vaccine virus, and that seroconversion to HRSV and HPIV3 occurred in 67% and 100%, respectively, of recipients of this vaccine dose.

HPIV1 and HPIV2 Vaccines

SeV, the murine relative of HPIV1, has been evaluated as a HPIV1 vaccine candidate in nonhuman primates and healthy adults. SeV was highly immunogenic and protective against HPIV1 challenge when administered intranasally to African green monkeys, and was well tolerated in adult human recipients and immunogenic in three of nine individuals.³³⁹

The replication of SeV was not significantly restricted in African green monkeys and chimpanzees compared to

HPIV1,³³⁵ which raises the possibility that it might not be satisfactorily attenuated in infants and children. However, SeV was attenuated in adults and is currently being evaluated as an experimental intranasal vaccine in young children (clinicaltrials.gov NCT00186927).

Live-attenuated candidate vaccines for HPIV1 and HPIV2 have also been developed based on the introduction of known attenuating mutations into cDNA-derived HPIV1 and HPIV2 by reverse genetics. In some cases, mutations were designed to have increased genetic stability, such as by choosing codons that could not revert by a single nucleotide substitution, or by deleting the relevant codon(s). One vaccine candidate, rHPIV1 84/del170/942A, contains mutations in the C, HN, and L proteins. Replication of this virus is highly restricted in adults and HPIV1 seropositive children. Evaluation of this vaccine in HPIV1 seronegative children is in progress (clinicaltrials.gov NCT00641017). Similarly, rHPIV2-15C/948L/Δ1724, an HPIV2 vaccine candidate, contains a mutation in the extragenic leader region of the genome, and an amino acid substitution and a deletion in the L gene. rHPIV2-15C/948L/Δ1724 is highly attenuated in African green monkeys yet protects against challenge with wt HPIV2.²⁷⁴ Replication of rHPIV2-15C/948L/Δ1724 is highly restricted in adults, and evaluation in HPIV2 seropositive children is in progress (clinicaltrials.gov NCT01139437).

PERSPECTIVE

The HPIVs continue to be an important cause of pediatric respiratory illness. There still are no approved antiviral therapies or vaccines for any of these viruses. The pathogenesis of serious HPIV disease such as croup, bronchiolitis, and pneumonia is still not well understood. Indeed, most of our understanding of HPIV infection, pathogenesis, and the host response is by inference from HRSV. In recent years, we have gained an understanding of the role of HPIV proteins in inhibiting the type I IFN response. Fewer advances have been made in characterizing the adaptive immune response to HPIVs, especially in infants and young children. However, significant progress has been made in the treatment of croup and in the development of HPIV vaccines. The natural histories of most of the animal PIVs remain poorly understood.

a highly neurotropic agent and a leading cause of virus-induced aseptic meningitis and encephalitis.^{20,42,190}

A number of laboratory investigations suggested that a filterable, transmissible agent was responsible for mumps^{141,281,423}; however, a viral etiology was not proven until 1935 when Johnson and Goodpasture, using bacteria-free parotid secretions, successfully transmitted the disease between monkeys and children and then back to naïve monkeys, fulfilling Koch's postulates.^{186,187}

The demonstration by Habel¹⁴⁵ and Enders¹⁰⁸ in 1945 that MuV could be isolated and propagated in embryonated eggs enabled the demonstration of the hemagglutinating, hemolytic,²⁶⁸ and neuraminidase¹⁸² properties of the virus, leading to the development of an inactivated vaccine in 1946¹⁴⁴ and to the first live virus vaccine in 1958.³⁵³ The introduction of tissue culture as a practical alternative for the propagation and study of the virus in 1948⁴¹⁴ was pivotal for advancing studies of the epidemiology and pathogenesis of the disease as well as the molecular biology of the virus, permitting the development of cell-based vaccines.

Although historically a benign disease of childhood, mumps was viewed as a major concern for the military, particularly in times of mobilization. Mumps was a notable issue during the Civil War of the United States,¹⁶⁶ World War I,¹³⁸ and during World War II,^{253,302} and continues to occur in military settings.^{13,218,316} During World War I, mumps was a leading cause of days lost from active duty in the United States Army in France, exceeded only by losses due to influenza and gonorrhea infections.

Use of live, attenuated mumps vaccines have nearly eliminated the disease from countries with high vaccine coverage rates of a two-dose regimen,^{126,301} although sporadic and sometimes large mumps outbreaks continue to occur even in highly vaccinated populations.⁹⁸

INFECTIOUS AGENT

Classification

MuV is a nonsegmented, negative-strand RNA virus in the family *Paramyxoviridae*, subfamily *Paramyxovirinae*, genus *Rubulavirus*. See Chapter 33 for a detailed overview of the *Paramyxoviridae*.

Virion Morphology and Structure

Mumps virions are pleomorphic particles ranging from 100 to 600 nm in size, consisting of a helical ribonucleoprotein (RNP) core surrounded by a host cell-derived lipid envelope (Fig. 35.1). The RNP consists of a single-stranded RNA

HISTORY

In the 5th century BC, Hippocrates described a mild epidemic illness associated with nonsuppurative swelling near the ears and, variably, with painful swelling of one or both testes. These descriptions of parotitis and orchitis, respectively, are the hallmarks of mumps virus (MuV) infection. The name *mumps* may derive from an old English verb that means to grimace, grin, or mumble. Hamilton, a physician of the late 18th century, is credited as being the first to associate central nervous system (CNS) involvement with mumps in his description of the neuropathology of a fatal case. Later studies would reveal MuV as

FIGURE 35.1. **A:** Pleomorphic mumps virions budding from a choroid plexus epithelial cell. **B:** A subjacent section processed for post-embedding localization of the major nucleocapsid-associated protein using monoclonal anti-N antibody. The N is localized by punctate, electron-dense reaction products below the surface membranes of the cell.

(ssRNA) molecule coated by the viral nucleoprotein.⁸² The RNP appears to be a hollow tube with a unit length of approximately 1 µm, a diameter of 17 to 20 nm, and a central core of 5 to 6 nm.^{168,169,251} The viral host cell-derived envelope contains the viral glycoproteins that project 12 to 15 nm from the virion surface.

Full-length genomic RNA (gRNA) is an unsegmented, single-stranded macromolecule of negative polarity that consists of 15,384 nucleotides. The presence of multiploid virions in MuV preparations has been reported, but only one of the genomes is believed to be biologically active.²⁵⁰

Genomic Organization

The MuV genome contains 7 tandemly linked transcription units: the nucleo- (N), V/phospho-/I (V/P/I), matrix (M), fusion (F), small hydrophobic (SH), hemagglutinin-neuraminidase (HN), and large (L) protein genes. The gene order is 3'-N-V/P/I-M-F-SH-HN-L-5'.^{105,107} The MuV genome is flanked at the 3' end by an extracistronic leader sequence of 55 nucleotides³⁷⁰ and at the 5' end by a trailer sequence of 24 nucleotides,²⁸⁸ of which the last 10 share inverse complementarity. These regions are essential for transcription and replication. Unlike most other paramyxoviruses, MuV does not have identical gene-start and gene-end sequences. The consensus gene-start sequence is 3'-U-U/C-C-G/U-G/U-N-C/U-U/C-U and that of the stop sequence is 3'-A-A/U-U/A-U-C/A-U-6-7,¹⁰⁵ separated from each other by intergenic sequences of 1 to 7 nucleotides.

Each gene encodes a single protein, with the exception of the V/P/I gene (conventionally referred to as the

P gene), which gives rise to additional mRNA species as a result of the cotranscriptional insertion of nontemplated G nucleotides between positions 461 to 466.^{107,297} Faithful transcription of the gene produces the V protein (formerly referred to as NS1 protein), whereas insertion of two G residues within the editing site produces an mRNA encoding the P protein and insertion of one or four G residues produces an mRNA encoding the I protein (formerly referred to as NS2 protein and analogous to the W protein reported in related paramyxoviruses). Thus, the V, P, and I proteins have the same amino-terminal segment but different C-terminal regions.

Genome transcription occurs by a stop-start mechanism in which the viral polymerase produces a decreasing gradient of monocistronic mRNA for genes located further from the 3'-end promoter (see Chapter 33). Due to the occasional failure of the viral RNA-dependent RNA polymerase (RdRp) to recognize the intragenic stop signals, bi-, tri-, tetra-, penta- and hexacistronic read-through transcripts can be detected in MuV-infected cells, from which only the first cistron is translated.^{5,89,106} The size of the monocistronic mRNAs as well as the number of amino acids and molecular weights of the MuV proteins are provided in Table 35.1.

Virus Proteins and Replication

N, P and L Proteins

The first translated transcriptional unit of the virus, the N protein, complexes with the gRNA to form the RNP, the template for RNA synthesis. Only encapsidated RNA, not naked

RNA, can be transcribed. RNA synthesis begins with the binding of the RdRp, a complex of the P and L proteins, to the RNP, as inferred from other studies of highly homologous viruses.^{140,147}

The MuV N protein is a bipartite molecule consisting of a globular N-terminal assembly domain (amino acids 1 to 398) mediating RNA binding (to form the RNP), and an unstructured hypervariable C-terminal tail believed, based on studies of related viruses, to interact with the MuV M protein during virion assembly.^{35,88,342}

The MuV P protein forms homotrimers via a centrally located coiled-coil domain⁸⁷ and complexes with the L protein to form the RdRp. The C-terminal 48 amino acids of the P protein is a nucleocapsid-binding domain (NBD), responsible for tethering of the RdRp to the RNP by binding to the assembly domain of the N protein (amino acids 1 to 398).²⁰⁷ The three-dimensional structure of the NBD has been deciphered using X-ray crystallography and revealed formation of a compact bundle of three α -helices, a feature that appears to be conserved among paramyxovirinae.²⁰⁸ Unlike the NBD of measles virus and Sendai virus, that of MuV lacks defined tertiary structure and is fundamentally unstable.²⁰⁷ As indicated by its name, the MuV P protein is heavily phosphorylated,²⁷⁸ an action believed to regulate polymerase activity, but this has not been clearly demonstrated for MuV.^{123,361,362}

Six functional domains have been identified in the MuV L protein based on sequence similarity with L proteins from related viruses.^{308,350} These domains have been ascribed all catalytic functions such as execution of transcription and replication, as well as methylation, capping, and polyadenylation of

mRNAs (see Chapter 33). A detailed functional and structural analysis of the MuV L protein has not yet been carried out.

Matrix Protein

The MuV M protein orchestrates virus assembly and budding. Only the MuV M protein when expressed alone is sufficient for virus-like particle production, although in the absence of co-expression with other viral proteins, efficiency is low.²³⁴ Evidence indicates that the M protein binds to the cytoplasmic tails of the F and HN glycoproteins assembled at distinct locations on cellular membranes, presumably lipid raft microdomains. There, the M protein functions as an adapter, physically linking the region of host-cell membrane expressing the viral F and HN glycoproteins with the viral RNP via its interaction with the N protein.^{152,234} Budding appears to be mediated by an interaction between the MuV M protein and the cellular endosomal sorting complex for transport (ESCRT) machinery.²³⁴ The MuV M protein has also been shown to interact with host proteins angiomin-like 1 (AmotL1) and 14-3-3.^{298,299} Whereas the AmotL1–M protein interaction appears to promote MuV VLP production, based on studies of PIV5, M protein interaction with 14-3-3 decreases the efficiency of virus budding. Interestingly, the MuV M 14-3-3 binding site is adjacent to a sequence motif conserved among rubulaviruses, presumably functioning as a binding site for the host protein caveolin 1 (Cav-1), an essential structural component of caveolae that are considered a subset of lipid rafts. It is therefore likely that MuV budding, like that of PIV5, occurs from caveolae. The close proximity of the 14-3-3 and postulated Cav-1 binding sites raises the possibility that the MuV

M protein switches between either binding to 14-3-3 or Cav-1, thereby regulating the amount of M that can participate in virus budding.²⁹⁹

Surface Glycoproteins

The F and HN are transmembrane glycoproteins of types I and II, respectively. The F glycoprotein is synthesized as an inactive precursor, F₀, that is targeted to the rough endoplasmic reticulum via a 19 amino acid signal peptide, which is subsequently cleaved.⁴⁰⁸ Following N-glycosylation, the precursor is transported to the trans-Golgi network where it is proteolytically cleaved between amino acids 102 and 103 by the host cell protease furin at the R-R-H-K-R motif to produce two disulfide-linked heterodimers F₁ and F₂.^{162,257,278,409} Cleavage of F₀ is essential for virus-to-cell and cell-to-cell membrane fusion and for virus infectivity. The amino terminus of the F₁ subunit possesses the fusion peptide, a conserved hydrophobic domain exposed by the cleavage event (see Chapter 33). Evidence indicates that a second cleavage event occurs during which F₁ is processed into two subunits, F_{1a} and F_{1b}; this event is important in mediating fusion activity.⁴⁰⁰

At least two heptad repeat (HR) domains are found in the F1 ectodomain: HR1 at the amino terminus adjacent to the fusion peptide and HR2 at the carboxyl terminus adjacent to the transmembrane domain.²³⁹ The MuV F protein forms homotrimers and the HR1 and HR2 domains interact to form a stable six-helix bundle structure.^{239,249} The HR2 domain is also involved in the binding of F with HN. In related viruses, additional HR domains have been identified, although this has not been confirmed for MuV.^{131,270} The specific processes involved in MuV fusion have not been delineated; however, based on similarity with the six-helix bundle structural of the PIV5 F protein, the events that mediate MuV fusion are likely similar to those for PIV5 (see Chapter 34).

In its native state, the HN protein is a disulfide-bonded oligomer assembled as homotetramers. The protein is held in the lipid bilayer by a hydrophobic domain of 19 residues near the amino terminal, a domain that probably also serves as a signal sequence in a manner similar to other paramyxovirus HN proteins. HN monomers display a membrane proximal stalk that supports a globular head, forming a six-blade propeller structure.^{84,219} The globular head is responsible for attachment and neuraminidase activity^{182,291}; the stalk region, in conjunction with the F protein, mediates virus-to-cell and cell-to-cell fusion.^{371,382} Based on inference from related viruses, a single site is believed to mediate both neuraminidase and receptor binding activity using a protein conformational switch mechanism to toggle activity.^{77,84,226} There may also be a second sialic acid binding site within the globular head region, theorized to stabilize viral–cellular membrane interactions in addition to the large binding pocket that fluxes between neuraminidase and receptor binding activity.^{37,314,437} Two competing models on the HN-assisted mechanism of F protein activation have emerged⁷⁸ (see Chapter 34 for details). Briefly, the “clamp model” proposes that the HN protein associates with F intracellularly, stabilizing the prefusion conformation of the protein. Upon binding of HN protein to its receptor, the F protein is released, allowing for the conformational change required for fusion activity. In the “provocateur model,” a change in the structure of the HN itself is postulated to promote fusion activity. In this model, the HN

protein either is preassociated with the F protein or associates with the protein following receptor binding, at which point the HN protein undergoes a conformational change leading to destabilization of the F protein, which confers fusion activity. Results from recent studies using PIV5 HN and F proteins support the “provocateur model.” Whether this model applies to MuV awaits confirmation.

V Protein

The MuV V protein, as reported for other rubulaviruses, is involved in inhibiting IFN production and signaling (see Chapter 33). The 69 aa C-terminal cysteine-rich domain of the MuV V protein appears to be the key player in these activities. This region directly interacts with MDA5 (melanoma differentiation-associated gene 5), a pattern recognition receptor that recognizes cytosolic viral RNA, and with the TBK-1 (TANK-binding kinase 1)/IKKε (inhibitor of κB kinase-ε) kinases responsible for interferon regulatory factor-3 (IRF-3) phosphorylation. MuV V protein interaction with MDA5 inhibits its ability to induce transactivation of the IFN-β promoter,^{12,320} and in the case of TBK-1/IKKε, leads to their ubiquitination and subsequent proteasomal degradation,²⁴³ preventing IRF-3 phosphorylation, an event required for transcription of IFN and IFN-stimulated genes. The C-terminus of the MuV V protein also interacts with the cellular signal transducer and activator of transcription (STAT) proteins, STAT-1, STAT-2, and STAT-3.^{151,282,434,435} STAT-1 and STAT-2 play a central role in the IFN signal transduction pathway that eventually leads to activation of IFN-induced genes. STAT 3 has also been implicated in cellular antiviral responses.^{318,389} Binding of MuV V leads to the ubiquitination and subsequent degradation through the proteasomal pathway of STAT-1 and STAT-3, but not of STAT-2; however, the latter is required for targeting of STAT-1 for degradation.^{216,388,389,435} The C-terminus of the MuV V protein is not the only region important in these interactions, as exemplified in a study demonstrating that a single point mutation at amino acid position 95 abrogates the ability of the MuV V protein to degrade STAT3, while retaining the virus's ability to target STAT 1.³¹⁸

The observation that the MuV V protein can oligomerize and form spherical particles suggests that the MuV protein provides a scaffold for coordinating the assembly of the cellular components (e.g., UV-damaged DNA binding protein 1 [DDB1], cullin 4A [Cul4A], and regulator of cullin 1 [Roc1]) involved in ubiquitination, collectively referred to as V-dependent degradation complexes (VDC).³⁸⁸ For more details on VDC, see Chapter 33.

SH Protein

The SH protein consists of 57 amino acids, 25 of which are highly hydrophobic and clustered at the amino terminus serving as a membrane anchor region with its C-terminus facing the cytoplasm.^{104,106,367} The predicted SH mRNA exhibits two AUG start codons, the second of which represents the actual AUG for the SH open reading frame. The first AUG, located at positions 4 to 6, gives rise to a minicistron with a stop codon at nucleotides 19 to 21.^{106,367} Due to the immediate proximity of the first cistron to the cap of the mRNA, it is predicted that with a frequency of about 50%, the ribosomes will skip the first AUG and initiate at the second cistron,²¹² thus enabling translation of the SH protein, although at reduced efficiency. The

biological significance of this minicistron and its proposed role in reducing the amount of SH protein synthesized is unknown.

In certain MuV strains, such as the Enders and Rubini strains, a point mutation exists in the putative F gene polyadenylation signal resulting in an F-SH bicistronic mRNA,^{220,367,368} from which only the F protein is made. This demonstrates that the SH protein is not essential for virus replication, which has been confirmed for PIV5.¹⁵⁶

Studies of PIV5 demonstrated that the SH protein facilitates evasion of the host antiviral response via blocking the TNF- α -mediated apoptosis pathway.^{156,157} The MuV SH protein appears to be functionally similar, based on recombinant DNA studies in which PIV5 SH gene was then replaced with that of MuV.⁴¹⁸ Yeast two-hybrid and co-immunoprecipitation studies identified ataxin-1 ubiquitin-like interacting protein (A1Up) as a cellular target of the MuV SH protein. This protein plays a role in proteasomal degradation, but the biological significance of its interaction with the MuV SH protein is not clear.⁴²⁷

I Protein

Expression of the I protein in infected cells was confirmed, but its role in the life cycle of the virus is unknown.²⁹⁷

Virus Infection of Host Cells

Sialic acid, an acyl derivative of neuraminic acid, is found on cellular glycoproteins and lipids and serves as the receptor for MuV. Following attachment of the virus to its receptor, the viral and cellular membranes fuse, permitting entry of the viral RNP followed by its transcription and replication. These events occur in a manner common to most paramyxoviruses (see Chapter 33 for a detailed description of these and other events such as viral assembly and release).

Because the MuV receptor is ubiquitously expressed on mammalian cells, the virus infects most cell types. The presence of MuV is typically detected in cell cultures by the induction of syncytia, large homogeneous masses of cytoplasm enclosing numerous nuclei (Fig. 35.2), followed by lysis of infected monolayers; however, the cytopathic effects of MuV can vary considerably among isolates and substrates, and in some instances, there is little evident morphologic change.^{4,142,250} The type of cytopathic effect produced *in vitro* does not correlate with the *in vivo* behavior of the virus.

PATHOLOGY AND PATHOGENESIS

Infection in Experimental Animals

Humans are the only natural host of MuV, although experimental infection has been induced in laboratory animals, including monkeys,^{230,327,334} hamsters,^{192,295,419} mice,^{205,295} and rats.^{315,331} Experimental infection of animals has mostly been used to study the pathogenesis of MuV neurotropism and neurovirulence. Intracerebral inoculation of MuV into the suckling hamster results in a massive inflammatory response, including meningitis, encephalitis, and ventriculitis. Intraperitoneal inoculation of virulent strains into suckling hamsters also leads to CNS infection.⁴²⁰ Associated neuropathology includes hydrocephalus, Chiari type I cerebellar malformation, and neuronal necrosis.^{204,295,366,369,421} Many of these are reported features of CNS infection in humans, suggesting the applicability of the hamster model for studying the pathogenesis of MuV infection in man. Similar findings have also been reported in monkeys.^{70,241,326,334,436} Very little, if any, work has been accomplished in mice because MuV infection in this species tends to be abortive, thereby limiting the value of this model system.^{155,317,383} Early studies also indicated mumps infection to be abortive in rats, unless adapted by serial passage in brain.³¹⁵ Subsequent studies, however, determined that intracerebral inoculation of the virus into newborn rats resulted in inflammation of the ventricular system (choroiditis, ependymitis) and hydrocephalus, but not meningitis or encephalitis.³³¹ Interestingly, the severity of hydrocephalus in rats was found to correlate well with the virus strain-specific neurovirulence potential for humans, suggesting the relevance of such a model of disease in examining the pathogenesis and molecular basis of MuV neurovirulence.³³² The severity of virus-induced neuropathology in marmosets, but not other monkey species, was also found to correlate with virus neurovirulence potential for humans.³²⁸

Infection in Humans

Transmissibility after nasal or buccal mucosal inoculation of virus¹⁸⁷ suggests that natural infection is initiated by droplet spread. The incubation period is 16 to 18 days,^{167,259} during which the virus multiplies in the upper respiratory mucosa before spreading to draining lymph nodes. Based on studies involving experimental infection of hamsters, virus disseminates via a transient plasma viremia,⁴²⁰ potentially infecting multiple tissues and

FIGURE 35.2. Phase contrast image showing the progression of typical cytopathic effects of a mumps virus clinical isolate after incubation on Vero cells for 1 (A), 4 (B), and 7 (C) days. The classic cytopathic effect of cell-to-cell fusion and syncytia formation (arrows) appear within a few days of culture, followed by cell lysis. By day 7 nearly the entire cell monolayer is consumed by syncytia and lysis. Acetone fixation, cresyl violet stain.

organ systems.¹⁷² The most common sites of virus dissemination are glandular tissues (parotid glands, testes, breasts, and pancreas), and the CNS. If viruria is used as an indication of kidney infection, then kidney involvement is common in mumps, although clinical nephritis is rarely diagnosed.^{392,394} In rare cases, MuV can be transmitted transplacentally.

Virus is shed in saliva as early as 6 days before the onset of parotitis.¹⁵⁹ Termination of viral shedding correlates with the local appearance of virus-specific secretory IgA and IgM, as early as a few days after disease onset.^{67,304} Fewer than 15% of patients continue to shed virus beyond day 4 of symptom onset.³¹⁰ Thus, patients with mumps are capable of spreading virus by the respiratory route over a 10-day interval.

Plasma viremia disappears coincident with the development of MuV-specific antibody, which can be detected in serum as early as 11 days after infection of humans.¹⁵⁹ Animal models suggest that circulating infected lymphocytes provide a means for the spread of virus in the face of mounting humoral immunity.⁴²⁰ Despite the apparent high frequency of viremia during mumps, MuV has only rarely been detected in blood.^{183,201,294}

Parotid Gland

Initial clinical symptoms usually relate to infection of the parotid gland, but viral involvement of this gland is neither a primary nor obligate step in the infection.²⁰² Virus infects the ductal epithelium, resulting in desquamation of involved cells, periductal interstitial edema, and a local inflammatory reaction primarily involving lymphocytes. Swelling, inflammation, and tissue damage in the parotid gland can produce elevation of serum and urine amylase levels.³⁴⁶

Central Nervous System

MuV CNS invasion, as demonstrated by cerebrospinal fluid (CSF) pleocytosis, occurs in greater than one third of patients presenting with clinical mumps.^{20,42,46,112} Symptomatic CNS infection (i.e., meningitis) is less common, occurring in approximately 10% of cases.^{20,149,198} Encephalitis occurs in less than 0.5% of cases. In the prevaccine era, MuV was a leading cause of viral meningitis and encephalitis in most developed countries and continues to be a leading cause in unvaccinated populations worldwide.^{18,125,160,258} Neurologic manifestations appear with a 3:1 or greater male–female ratio^{30,210,228} and are generally preceded by parotitis by 4 to 5 days but can occur before or in the total absence of detectable salivary gland swelling.

As inferred from animal studies, viral invasion of the CNS occurs across the choroid plexus.⁴²⁰ Blood-borne infected mononuclear cells, and possibly cell-free virus, can cross the fenestrated endothelium of the choroid plexus stroma and serve as a source for subsequent infection of the choroidal epithelium. Maturation of virus from the ventricular surfaces of choroidal cells provides progeny virions that are widely distributed through ventricular pathways and the subarachnoid space by CSF (Fig. 35.3). Virus can penetrate brain parenchyma and infect neurons by contiguous spread from infected ependymal cells that line the ventricular cavities of the brain. Once within neurons, virus most likely spreads along neuronal pathways, as reported in nonhuman primates.²³⁰ Although primary encephalitis is typically the response to direct viral invasion of neural cells, cases of postinfectious encephalitis, an autoimmune attack on CNS myelin sheaths, also occurs. Symptoms of primary encephalitis appear before or during the develop-

ment of parotitis; symptoms of postinfectious encephalitis and associated demyelination appear 1 to 3 weeks after the onset of parotitis.^{238,372}

Typical CNS pathology of MuV encephalitis includes edema and congestion throughout the brain with hemorrhage, lymphocytic perivascular infiltration, perivascular gliosis, and demyelination. Findings in the spinal cord include early degenerative changes in the anterior horn cells and perineuronal edema.^{102,264,372} When seen, the selective periventricular myelin loss with relative sparing of axons is typical of parainfectious autoimmune encephalitis.

Rarely is CNS infection fatal and most cases resolve without sequelae. In some instances, however, electroencephalographic changes, ataxia, and behavioral disturbances may take months to resolve^{173,210} and permanent neurologic damage—such as obstructive hydrocephalus,²⁸⁶ deafness,²³⁶ and myelitis^{284,395}—can occur.

Hydrocephalus can develop days to years after initial MuV infection and can lead to progressively worsening headaches, mental status changes, and gait abnormalities.^{71,137,286} The pathogenesis of hydrocephalus is inferred from animal studies that have suggested that desquamation of virus-infected ventricular ependymal cells blocks egress of CSF through the aqueduct of Sylvius. Abnormally restricted flow of CSF to adsorptive sites over the cerebral convexities results in progressive enlargement of the lateral and third ventricles.^{191,192} The presence of ependymal cell debris in the CSF of humans presenting with MuV CNS infection suggests a similar mechanism of hydrocephalus induction in humans.^{161,286,380} Hydrocephalus, however, has also been observed before, or in the total absence of, aqueductal stenosis.^{189,364,365,419} This indicates that stenosis of the aqueduct could be a secondary consequence of external compression by surrounding edematous tissue and not causally related to the pathogenesis of hydrocephalus.

MuV is the most frequent cause of acquired sensorineural hearing loss in children. Transient, high-frequency deafness is the most common form, occurring in approximately 4% of mumps cases.⁴⁰² Permanent deafness occurs in less than 1 per 20,000 cases^{27,153} and is usually unilateral. Deafness is believed to be the result of direct viral invasion of the cochlea, likely via the perilymph, which freely communicates with the CSF^{146,254,352,415}; however, evidence indicates a hematogenous route exists.²⁶⁵ Pathology includes degeneration of the stria vascularis, tectorial membrane, and organ of Corti and collapse of Reissner's membrane.¹¹¹ Hearing loss caused by indirect effects of virus infection (e.g., immune-mediated damage) have also been suggested.³⁹⁰ Deafness is not disproportionately seen with other complications, suggesting no specific pathogenic link with parotitis, meningitis, or other complications. Deafness has also been observed in otherwise asymptomatic patients.^{287,390}

Gonads

Orchitis, usually unilateral, occurs in approximately 20% of postpubertal men who develop mumps.^{16,124,224} Orchitis rarely occurs in children, suggesting that certain hormonal factors, such as receptors for luteinizing hormone and follicle-stimulating hormone expressed during adolescence, might promote testicular tropism of the virus.³⁷⁶ Virus has been isolated from testicular biopsies of the affected gland within the first 4 days of symptoms, and from semen,^{29,179} strongly suggesting that symptomatic gonadal involvement reflects local virus replication. The

FIGURE 35.3. Post-embedding electron-microscopic immunocytochemical staining of a region of the lateral ventricle of a hamster 5 days after intraperitoneal infection with the Kilham strain of MuV. Anti-N monoclonal antibody was used as the primary reagent. The reaction product defines nucleocapsids located below the cytoplasmic membranes at sites of virion budding along both the ependymal and choroidal (unfilled arrows) surfaces. Intracytoplasmic nucleocapsid inclusions are also demarcated by the reaction product in both choroid plexus and individual ependymal (filled arrow) cells.

seminiferous tubules may be the primary site of viral replication, with local lymphocytic infiltration and edema of interstitial tissues.

Ovary infection is diagnosed in less than 5% of postpubertal women who develop mumps,^{38,64,97,199,248,360} which may be an underestimate because unless a pelvic examination is performed, abdominal or pelvic pain from inflamed ovaries might be attributed to pancreatic infection.

Kidneys

Based on the frequency of viruria, virus frequently disseminates to the kidneys, where epithelial cells of the distal tubules, calyces, and ureters appear to be primary sites of virus replication.⁴¹³ Viruria can be detected in most patients, sometimes for as long as 14 days after the onset of clinical symptoms.^{392,393} Mild abnormalities of renal function have been described, but they are usually of little clinical importance.³⁹² Although virus dissemination to, and replication in, the parotid gland and kidney can occur simultaneously, replication in renal tissue is more prolonged and continues well beyond the appearance of neutralizing antibody in serum.

Pancreas

Pancreatic involvement, diagnosed in 1% to 27% of cases,^{38,47,64,232,296,345,356,376,416} is usually expressed as mild epigastric pain,

but severe hemorrhagic pancreatitis¹¹⁴ and transient exocrine function abnormalities⁹² have been reported. MuV infects human pancreatic beta cells *in vitro*,⁴⁰³ and virus infection of the pancreas has been demonstrated in hamsters inoculated intraperitoneally.⁴²⁰ Viral infections have been considered a possible precipitating event leading to the onset of about one third of all cases of juvenile-onset or type I insulin-dependent diabetes mellitus (IDDM); however, whether MuV causes IDDM is unclear.^{83,127,136,344} No association has been found between mumps and type II diabetes.²⁴⁰

Heart and Joint Tissues

Myocardial invasion occurs frequently in mumps, as indicated by electrocardiographic abnormalities.¹⁴ Although it is seldom symptomatic, interstitial lymphocytic myocarditis and mild pericarditis may occur following mumps replication in cells of the myocardium and pericardium.⁴³ MuV myocarditis can lead to the rare but serious sequelae of endocardial fibroelastosis.²⁷⁹

Mild to moderately severe mono- or polyarticular and, often, migratory arthritis has rarely been associated with mumps.¹³⁹ MuV has not been isolated from joint fluids or synovial tissues, and no evidence exists for significant immune complex deposition.

Fetus and Newborn

MuV can be transmitted transplacentally as demonstrated in nonhuman primates³⁵⁷ and by the isolation of the virus from the human fetus following spontaneous first-trimester abortion during maternal mumps.^{221,433} The virus can produce a fetal wastage in humans, with or without subsequent spread of virus to involve fetal tissues directly.⁴³³ MuV has also been isolated from fetal tissues following planned therapeutic abortion of seronegative women 1 week after vaccination with live, attenuated MuV, although it is unclear if the virus detected was vaccine virus, or wild-type virus coincidentally contracted at or shortly before the time of vaccination.⁴³⁰ A proliferative necrotizing villitis with decidual cells containing intracytoplasmic inclusions has been described in the products of spontaneous and induced abortions.¹²⁹ Late-gestation intrauterine infection was reported in an infant born to a mother who developed mumps more than 4 weeks before delivery, diagnosed by reverse transcription polymerase chain reaction (RT-PCR) testing of the infant's cord blood cells.³⁶³ This infant developed severe pulmonary symptoms, including hypertension and hemorrhage.

MuV is excreted in breast milk,²⁰³ but few cases of perinatal mumps have been described^{195,222} and it is not clear if breast milk was responsible for these cases. There appears to be a somewhat different mode of pathogenesis of mumps in newborns. In the first year or two of life, infants may have only pulmonary involvement without evidence of parotitis.^{195,363} Split immunologic recognition in the infants can follow maternal parotitis, resulting in MuV-specific cell-mediated immune responses without a concomitant antibody response.^{1,357,378}

Molecular Basis of Virulence

While comprehensive studies on the molecular basis of MuV virulence have yet to be performed, it is clear that the genetic basis of MuV neurotropism and neurovirulence does not lie within any one gene^{7,329,339,348,428} and no simple pattern of genomic mutations capable of discriminating virulent from attenuated MuV strains has been identified.^{8,177,339}

CLINICAL FEATURES

The clinical features of mumps reflect the pathogenesis of the infection, as reviewed here. Approximately one third of all MuV infections occur without recognized symptoms.^{44,79,112,305,321} Moderate fever is often present at the onset of disease, with defervescence a few days later. The feature most characteristic of mumps is salivary gland swelling, particularly the parotid glands (Fig. 35.4),³⁰⁵ which constitutes the basis of a clinical diagnosis. Submaxillary gland enlargement and involvement of the sublingual glands also occur. Enlargement of individual glands is painful, usually lasting 2 to 3 days, but may persist 10 days or longer.¹⁵⁸ Virus is present in the saliva for several days before the onset of clinical disease¹⁵⁹ and for up to 5 days later.⁶⁷ The virus can be detected in urine for several weeks after the onset of mumps.³⁹³

Various organs and tissues can be symptomatically involved during mumps, including the testes, CNS, mammary glands, ovary, pancreas, kidneys, and heart.¹⁷² Parotitis usually precedes manifestations of involvement of other sites of virus infection, but the latter can be clinically evident before, during, or even in the absence of parotitis.

FIGURE 35.4. Child with parotitis. (Courtesy of Centers for Disease Control and Prevention, Atlanta, GA.)

The most common complication of mumps (aside from parotitis) is epididymo-orchitis. Testicular pain and swelling has a time course similar to that of the parotid gland. Mumps orchitis often leads to testicular atrophy of the involved and, occasionally, the clinically uninvolved gland.²⁵ Atrophy after mumps orchitis is rarely implicated as a cause of male sterility.³⁴⁹ About 15% of females complain of breast swelling and tenderness. As with orchitis in men, the incidence of mastitis is significantly higher after puberty.³⁰⁵

Nausea and vomiting with or without epigastric or left upper-quadrant pain are frequent features of mumps, occurring in approximately half of all cases during the St. Lawrence Island epidemic.³⁰⁵ It is unclear whether these symptoms reflect involvement of the pancreas or other viscera. Some of these generalized features of the illness may reflect the effects of circulating IFN, which can be found in serum early in the clinical course of mumps.^{269,404}

More than one third of mumps cases develop CSF pleocytosis, but symptomatic CNS involvement is far less frequent.^{20,42,305} Mumps meningitis may precede parotitis, but it typically develops 5 days following parotitis. However, as many as half of those with mumps meningitis may not have detectable salivary gland enlargement.^{193,202}

IMMUNE RESPONSES

Humoral Immunity

Virus-specific salivary IgM and IgA and serum IgA, IgM, IgG, and neutralizing antibody are all detectable at the time of symptom onset. During natural infection, salivary IgM appears to be the first detectable immunoglobulin class, followed by salivary

IgA. The latter is capable of virus neutralization and is detectable for approximately 10 weeks after symptom onset.^{68,119,120} Levels of serum IgA and IgM peak approximately 1 to 2 weeks after symptom onset and decline to undetectable levels by week 8 after symptom onset.^{41,387} MuV-specific IgG has been detected as early as 4 days before symptom development,²⁸⁰ peaking 4 to 8 weeks later and detectable for decades.^{41,387} In naïve individuals, IgG is of low avidity²⁷⁷ and IgG3 antibodies predominate early in the course of disease, whereas in later stages isotypes IgG1 and IgG2 predominate. Upon a second exposure to MuV, serum IgM and IgA antibodies are typically absent or are produced at very low levels; the IgG1 subclass, typically of high avidity, predominates.¹⁴³

Virus-neutralizing antibodies, which are a correlate of protection, are detectable as early as day 2 after symptom onset, peaking 4 to 8 weeks later, and are detectable for decades. Studies conducted during the prevaccine era indicate that neutralizing antibody titers in the range of 1:4 to 1:8 confer protection,^{23,44,109,260} however, it is not clear if such low levels of vaccine-induced neutralizing antibody are protective. Studies of the effectiveness of the Jeryl Lynn mumps vaccine strain conducted shortly after licensure in the United States indicate that neutralizing antibody titers as low as 1:2 are protective.^{410,411} However, in a more recent study conducted among Jeryl Lynn vaccinees involved in a mumps outbreak, many confirmed mumps cases had neutralizing antibody titers in excess of 1:8 in preoutbreak blood samples.⁸⁰

Only antibodies directed against the F and HN protein have been definitively shown to neutralize the virus and protect against infection.^{170,235,242,354} Use of polyclonal antisera in virus neutralization assays demonstrates a broad cross-reactivity among different MuV genotypes.^{176,291,293,333,431} However, neutralizing antibody titers can differ substantially against different MuV strains, suggesting the existence of virus strain-specific neutralizing epitopes. Despite such demonstrations in the laboratory, MuV appears serologically monotypic in clinical situations as suggested empirically by the dramatic reductions in mumps incidence in countries with high two-dose vaccine coverage.^{126,300,351,407}

The role of antibody in arresting the infection cannot be underestimated. Seropositive patients challenged intravenously with up to 10^9 plaque-forming units of MuV showed only transient fever and no symptoms of reinfection developed, although an anamnestic rise in antibody titer was seen 4 to 5 days later.²⁸⁹ Animals are protected from otherwise lethal viral challenge by neutralizing monoclonal antibody administered several days after primary virus inoculation.⁴²² The development of hemagglutination-inhibition and virus-neutralizing antibody responses in the hamster model correlates well with the fall in peak virus titers in infected organs. In hamsters, however, viral antigens continue to be expressed, and clinical CNS disease actually occurs, after virus titers have fallen considerably.⁴²⁰

Cell-Mediated Immunity

In vitro lymphocyte-proliferative responses to MuV antigens are readily measured in seropositive individuals.¹⁷⁴ CD8+ and γ/δ cytotoxic T lymphocytes have been demonstrated in blood and CSF following infection with wild-type or vaccine MuV strains.^{26,69,116,215} Mononuclear cell inflammation in MuV-infected tissues is well developed at the time of onset of clinical disease, suggesting that specific cellular responses develop

during the incubation period. The presence of major histocompatibility (MHC) antigen (e.g., MHC Ia)-restricted T lymphocytes and specifically sensitized cells in both the blood and the CSF of some patients with active mumps meningitis support this view.¹²¹ After immunization, peak cell-mediated immune responses are found 2 to 4 weeks later and can last for decades.^{69,150,194} Circulating cytotoxic T-cell responses restricted to autologous infected target cells are found within the first few weeks of mumps meningitis.

Although the presence or absence of MuV-specific cell-mediated responses often correlates with the presence or absence of virus-specific antibody, the magnitude of the two types of immune responses do not correlate^{66,324}; in some instances, cell-mediated immune responses have been detected in seronegative persons.^{150,194} Immunologic studies of related viruses (e.g., measles) indicate the importance of the cellular response in the recovery and long-term protection from disease,^{24,128,180,181,303,405} but this has not been established for MuV. For example, levels of interferon- γ induced by MuV infection do not correlate with illness severity^{223,404} and patients with severely compromised T-cell responses experience a course of disease that does not differ from that seen in healthy individuals.⁹⁹ Similarly, neither severe symptoms of mumps nor a protracted course of illness has been reported in persons with AIDS.

Considering data demonstrating that MuV targets mda-5 and STAT proteins for degradation (discussed earlier), MuV may impede cytotoxic T lymphocyte (CTL) activation, by suppressing IFN production and signaling, which regulate MHC class-I expression.⁴⁹

EPIDEMIOLOGY

Age

Before widespread vaccine use, mumps was most commonly seen in children between 5 and 9 years of age⁷⁶; by 15 years of age, greater than 90% of most populations had serologic evidence of infection with MuV.^{52,271} Despite a high seroprevalence in older individuals in the prevaccine era, large outbreaks were common, particularly in high-density, close-contact environments, such as military settings.^{138,302}

In the years following mumps vaccine licensure in 1967, a gradual shift was seen in the typical age of infection in the general U.S. population from young children towards those 10 to 19 years of age, likely reflecting protection of younger children by vaccination, while older children and young adults not eligible for vaccination at the time remained susceptible.^{54,396} By 1992, the highest age-specific incidence in the United States shifted back to the 5- to 9-year-old age group, where it remained until a large multi-state mumps outbreak occurred in 2006, predominantly on university campuses.^{255,256} In the years following the 2006 mumps outbreak, the age-specific incidence returned to the younger age group,^{58,59} until the recent mumps outbreaks in New York and New Jersey in 2009–2010, where again most cases occurred in young adults.⁶⁴ A similar pattern has been observed in many other countries and the occurrence of mumps predominantly in young adults is now common.

Mumps is rarely seen in children younger than 1 year of age, most likely because of acquisition of immunity by placental transfer of maternal antibody. In premature infants born to seropositive mothers, little maternal antibody can be detected

at birth; by 3 months of age, no antibody can be detected in these babies.¹³³ Thus, premature infants may be particularly susceptible to MuV infection.

Morbidity and Mortality

The major morbidity from mumps results from meningitis, encephalitis, and orchitis. These occur as age- and sex-specific hazards, with peak risk in postpubertal boys.¹⁰ With the case fatality ratio for mumps between 1.6 and 3.8 per 10,000,⁵¹ and with 0.5% to 2.3% of all mumps encephalitis cases being fatal,²⁶⁶ it is apparent that most fatal mumps cases have CNS infection.

Origin and Spread of Epidemics

Humans are the only natural host for MuV infection; there is no known animal reservoir. MuV, as with measles virus, requires a population of about 200,000 people to sustain its continued transmission. Such population densities were first achieved some four to five millennia ago,³¹ so it follows that MuV first evolved about 5,000 years ago. Presently, mumps is a geographically unrestricted disease, except for its absence among a few remote tribes or isolated small-island populations. In modern-day urban populations and in the absence of immunization, mumps is endemic, with peak incidence rates in the winter and spring months.²⁶⁶ In the prevaccine era, preschool-aged children were an important source of virus introduced into families, given that inapparent infections are common in children of this age.^{79,305}

In the present era of high vaccine coverage of children, most cases now occur among young adults, suggesting waning immunity. Indeed, levels of MuV-specific antibody decline significantly with time after vaccination,^{36,40,94,96,227,263} and time since last vaccination has been identified as a factor in decreased vaccine effectiveness^{75,122,345} and in increased odds of contracting disease.^{48,81,397}

Prevalence and Seroepidemiology

Data on the incidence of mumps are complicated by the fact that approximately 30% of all MuV infections are subclinical.^{44,79,112,233,246,305,321} Furthermore, only 25% of all cases are seen by a clinician and fewer than 30% are reported to public health agencies.^{112,233} Annual incidence rates vary, with an interepidemic period of approximately 3 years.^{10,22,283}

The highest incidence of mumps reported in the United States since 1922 was almost 250 per 100,000 population in 1941. In 1968, when mumps vaccine was introduced, the yearly incidence was 76 per 100,000 population, steadily declining to less than 1 case per 100,000 population by 1993 and then to an all-time low of less than 0.1 case per 100,000 population by 2003 (Fig. 35.5).^{51,56} Mumps incidence remained low until 2006 when the United States experienced its largest mumps outbreak in 19 years, with 6,584 cases reported, representing a 20-fold increase in disease incidence from the prior year. Mumps incidence rapidly returned to baseline, before another large outbreak occurred in 2009,⁶³ suggestive of a possible return to the 3-year interepidemic cycle.

In the prevaccine era, or in countries not incorporating mumps vaccine in national immunization programs, most persons become seropositive by adolescence. In the United States, where vaccination is required for school entry, by 1996, approximately 90% of 19- to 35-month-old children had received at least one dose of mumps-containing vaccine^{50,57,62} and among adolescents aged 13 to 17 years, by 2006 coverage with two or more doses was 89%.⁶¹ These figures are close to the herd immunity threshold, estimated to be 90% to 92% based on theoretical studies,^{11,306} but are lower than the 95% figure based on evidence from the experience in Finland where indigenous mumps has been eliminated.⁹⁵

MuV was the most common cause of viral encephalitis in the United States until 1975, following attainment of high coverage rates of vaccination.⁵⁵ In unvaccinated populations,

FIGURE 35.5. Mumps cases per 100,000 population in the United States from 1922 to 2010. Vertical line indicates year of vaccine introduction (1967). **Inset:** Larger scale showing disease incidence between 1985 and 2010, with large outbreaks in 1987–1989, 2006, and 2009–2010.

FIGURE 35.6. Phylogenetic tree showing the 12 MuV genotypes, A through L, based on the *SH* gene nucleotide sequence. Strains in bold type have been suggested as international reference strains for the respective genotypes.¹⁸⁴ The tree was constructed based on comparison of coding sequences of *SH* gene using the OligoScan (Micro-Tech, S. Hutchinson, KS) custom computer software package. The algorithm uses nucleotide distance matrix and clustering based on the Pearson correlation coefficient between lines of the matrix. (Tree constructed courtesy of Dr. Konstantin Chumakov, FDA/CBER.)

mumps accounts for up to half of all encephalitis cases.³¹¹ In an epidemic setting, 11% of clinical mumps cases have CNS disease, 90% with meningitis and 10% with encephalitis.³⁰⁵ Severe mumps meningitis or encephalitis is most common between the ages of 5 and 9 years, with a clear male predominance in all age groups.³⁰

New Epidemiologic Approaches

The most significant molecular epidemiology advance has been RT-PCR to identify and group individual virus strains by related genomic sequences. RT-PCR analysis has become a key element in mumps surveillance and is a definitive means of identifying transmission pathways. MuV genotyping is conventionally performed based on the nucleotide sequence of the *SH* gene, the most variable sequence in the genome. Phylogenetic analyses of these sequences place the virus strains into distinct clusters that form the basis for genotype assignment.⁴³² Virus strains belonging to the same SH genotype vary at the nucleotide level within the SH gene by up to 4%, whereas intergenotype variation is typically on the order of 8% to 19%.^{184,185} It has been suggested that establishment of new genotypes be based on variation from existing genotypes by greater than 5% at the nucleotide level, among other criteria.^{184,185} Currently, 12 MuV genotypes exist, designated A through L (Fig. 35.6). A provisional genotype M has been proposed.³³⁶ Because of the lack of a central body for assigning genotype designations, some confusion exists to which strains are members of genotype J and which are members of genotype K. Genotypes A, C, D, G, and H are predominantly observed in the Western hemisphere, whereas genotypes B, F, I, J/K, and L are typically found in countries of the Asia-Pacific region.²⁷² Cocirculation of multiple genotypes within a region, or even within an outbreak, is not uncommon. There is no established association between genotype designation and specific virus characteristics,^{8,177,339} although some have suggested that virus genotypes C, D, H, and J are more neurotropic than other genotypes.^{319,373,375}

Relationships among MuV strains have also been inferred from nucleotide sequence analyses of the *N*,¹⁷⁸ *P*,^{335,429} *F*,^{118,374,385} and *HN*^{229,330,431} genes. While these genes are more conserved in sequence and, thus, their use in discriminating among virus strains is not as powerful, phylogenetic analyses of these sequences may prove useful. For example, because the HN protein is the major cell surface target of neutralizing antibody,^{291,292,347} it stands to reason that HN-based genotyping will provide valuable information on antigenic diversity and protective immunity.^{91,211,293} Sequence analysis of this and other genes may also provide valuable information on the evolution of MuV.

RT-PCR and sequencing of viruses has proved particularly useful in investigation of possible vaccine-associated adverse events, such as aseptic meningitis. It was not until the availability of this technology that reports of this complication of vaccination could be confirmed.^{17,196,273,275,340,377,401}

DIAGNOSIS

Clinical Diagnosis

A clinical diagnosis of mumps is made on the basis of fever and constitutional symptoms (e.g., parotitis) usually developing within 3 weeks after known exposure. Meningeal symptoms

include headache, vomiting, fever, and nuchal rigidity, usually appearing 3 to 5 days after the onset of parotitis with a range of 1 week before to 2 weeks afterward.^{20,322} Seizures occur in 20% to 30% of patients with CNS symptoms.^{19,132} Meningeal involvement is also suggested by positive Brudzinski's and Kernig's signs and can be differentiated from encephalitis by a normal electroencephalogram (EEG), although the EEG findings can be normal in subjects with encephalitis, even when clinical seizures occur.¹³² In many cases, the diagnosis can be confirmed by an elevated CSF-to-serum antibody ratio.^{269,387} Mumps meningitis is generally a benign condition with complete recovery in 3 to 4 days. Frank delirium and focal neurologic deficits are uncommon. Patients with mumps meningitis and encephalitis without focal deficits, prolonged or recurrent focal seizures, or papilledema have marked clinical improvement of neurologic function within 2 to 4 days. Even with profound obtundation, patients recover with few sequelae.^{19,42,46}

Laboratory confirmation is often required because a number of infectious agents, drugs, and conditions can cause mumps-like symptoms (see Differential Diagnosis below).

Laboratory Diagnosis

Laboratory diagnosis presently rests on infectious virus isolation (typically using Vero cells), detection of viral genome by RT-PCR, and appropriate serologic studies of acute and convalescent sera.

Infectious virus and virus genome can be detected in several clinical fluid specimens, including oral fluid samples (e.g., saliva, throat swabs, and buccal swabs), CSF, and urine. Specimens should be collected as early in the disease as possible (within the first week) with storage at -70°C or below until testing can occur. Success rates are highest with oral fluid samples and lowest with urine and blood samples, despite the apparent high frequency of viruria and viremia.

Studies using oral fluid specimens demonstrate that MuV isolation by cell culture is as sensitive as detection by RT-PCR.^{33,213,267,325} For urine, however, success rates are higher for virus isolation as compared to RT-PCR detection, possibly due to the presence of PCR inhibitors in urine,^{3,154,213,267,426} and for CSF, for reasons that are not clear, success rates are higher for RT-PCR.^{309,384}

The relative success of virus detection also appears to depend on vaccination status. Whereas the success rate of virus detection in cases with a history of 0 or 1 dose of vaccine typically exceeds 70%,^{3,90,267} in persons with a history of 2 doses of vaccine, virus could only be detected in approximately 30% of clinically apparent cases.^{28,325}

Many of the viruses in the differential diagnosis of mumps cause cellular pathology indistinguishable from that induced by MuV, and not all MuV strains produce cytopathic effects *in vitro*. Therefore, cultures must be tested for the presence of virus antigen by immunocytochemistry on cells inoculated with clinical specimens, or for viral genome by RT-PCR. Direct testing of clinical specimens by RT-PCR without an intervening cell culture step is commonly practiced.

Mumps humoral immune responses are most commonly measured by ELISA or virus neutralization. Other once commonly performed serologic tests, including complement fixation, immunofluorescence assay, hemagglutination-inhibition and hemolysis-in-gel are no longer widely used due to inferior sensitivity and specificity (i.e., cross-reactivity with other

paramyxoviruses). Because most people either have a history of vaccination or natural infection, simple detection of MuV antibodies in patient serum is not sufficient for a diagnosis of acute infection or reinfection. Rather, a significant rise in antibody titer relative to that in serum drawn before or at the onset of symptoms (e.g., as neutralizing antibody or ELISA-based IgG) needs to be demonstrated in convalescent serum drawn 2 to 4 weeks after the onset of clinical symptoms. Alternatively, MuV IgM and IgG levels can be compared when only acute-phase serum is available. The MuV-specific IgM response will exceed the IgG response early in the infection before diminishing over the next few weeks to months.³⁸⁷ In the present era of high vaccine coverage, reliance only on IgM detection is no longer advised, given the difficulty of its detection in anamnestic immune responses.^{154,337,338} Thus, in vaccinees, the absence of MuV-specific IgM is not confirmation of the absence of MuV infection. Furthermore, testing of sera too early or too late in the course of disease can also yield false-negative IgM results.^{86,214,406}

Because of its ease of use and high throughput, ELISA is more often performed than the labor-intensive virus neutralization assay. However, antibodies without known biological activity (e.g., those directed against the MuV nonstructural proteins) as well as cross-reactive anti-parainfluenza virus antibodies yield a positive result in the MuV ELISA, raising concern with interpretation of ELISA-based results in certain settings.

White blood cell (WBC) and differential counts are usually normal although leukocytosis is common in cases presenting with meningitis, orchitis, or pancreatitis. Serum amylase levels are elevated in cases of parotitis or pancreatitis, the latter being differentiable from parotitis by isoenzyme analysis or serum pancreatic lipase determinations.²³⁸

In cases of CNS invasion, lymphocytes are the predominant cell type found in the CSF, with WBC counts averaging 250/mm³.^{202,424} Cells counts peak around the third day of neurologic symptoms and then gradually decline over a period of several weeks.^{121,417} In some instances, CSF pleocytosis can persist for as long as a year.³⁹⁸ The CSF is usually under normal pressure⁴⁶ and the protein content in the CSF is elevated in 60% to 70% of all cases.^{121,202} Protein levels up to 100 mg/dL can be seen; on occasion, they exceed 700 mg/dL. This appears to reflect damage to the blood-brain barrier, as indicated by elevated albumin indices that do not normalize for several weeks to months after the onset of CNS symptoms.²³⁷ The CSF glucose content is modestly depressed to 17% to 41% of the serum value in 6% to 29% of all cases.^{101,193,417} About one third of all patients have evidence of intrathecal IgG synthesis and demonstrable oligoclonal immunoglobulins during the first week of CNS symptoms; this oligoclonal antibody can persist for more than 2 years.¹²¹ More than one half show increased IgG indices by the third month following mumps meningitis.^{121,237,399} Up to 90% of patients with acute mumps meningitis produce virus-specific IgG within the CNS compartment,^{237,387,399} and one half show MuV-specific IgM.¹¹⁷ Because mumps antibodies are uncommon in the CSF during other CNS infections,¹⁰⁰ in many instances of mumps meningitis, a diagnosis can be confirmed by elevated CSF-to-serum antibody ratios using samples taken during illness.^{269,387}

Of all cases of mumps with symptoms sufficiently severe to warrant hospitalization, less than 10% can be expected to show transient electrocardiograph abnormalities consistent

with myocardial damage. These usually consist of ST-segment depression, but patients can show evidence of atrioventricular conduction defects, including complete heart block.¹⁴ Seldom is the cardiac involvement acutely symptomatic. MuV myocarditis can be linked, however, to serious long-term sequelae, such as endocardial fibroelastosis.²⁷⁹

DIFFERENTIAL DIAGNOSIS

When parotitis is present, the clinical diagnosis of mumps is straightforward, even if the disease is not epidemic. Nonetheless, other causes of parotitis should be considered. These include parainfluenza virus types 1 and 3, influenza A virus, coxsackievirus, lymphocytic choriomeningitis virus, human immunodeficiency virus (HIV), and suppurative infections including *Staphylococcus aureus* and atypical mycobacteria. All can be easily differentiated from MuV by serology or culture. Starch ingestion, drugs (e.g., phenylbutazone, thiouracil, iodides and phenothiazines), metabolic disorders (e.g., diabetes mellitus, cirrhosis, and uremia), and malnutrition can also cause parotitis. Rare conditions such as Mikulicz's, Parinaud's, and Sjogren's syndromes can also be confused with mumps.²³⁸ Other possible causes of parotid swelling include tumors, cysts, and salivary stones. Without parotitis or with inconspicuous salivary gland enlargement, symptoms of other visceral organ or CNS involvement may predominate, thus laboratory confirmation of the diagnosis is required, even during an epidemic.

TREATMENT

Treatment of mumps and its various complications is generally symptomatic. In a controlled study, adult men presenting with parotitis were alternatively given either an intramuscular injection of 20 mL of gammaglobulin prepared from human convalescent serum or simply confined to a hospital for routine, nonspecific symptomatic therapy.¹³⁰ Orchitis developed in 4 of 51 antibody-treated and 14 of 51 symptomatically treated patients ($P < 0.01$). No protective effect was seen with gammaglobulin obtained from a normal donor serum pool.¹³⁰ This study suggests that immunotherapy with high-titer polyvalent or monoclonal antibody preparations could be useful in selected cases but should be used very early in the course of the illness. Notably, immunoglobulin for the treatment of mumps is no longer available in most countries.

PREVENTION AND CONTROL

The apparent ineffectiveness of passive protection and the near impossibility of preventing virus spread by case isolation (considering that virus is shed before the appearance of clinical symptoms and a significant portion of infected individuals are asymptotically infected) leaves vaccination as the only practical control measure.

Vaccines and Adverse Events

Two general types of MuV vaccines have been used, formalin-inactivated (killed) vaccines and live, attenuated vaccines. Use of formalin-inactivated MuV vaccines (used in the

TABLE 35.2 Mumps Virus Vaccine Strains in Current Use

Vaccine strain	Genotype	Manufacturer	Vaccine name	Main area of use

^aIn development

United States from 1950 to 1978) has been discontinued worldwide due to short-lived (<1 year) immunity and relatively poor efficacy.^{175,307} All mumps vaccines currently in use are composed of live, attenuated virus (Table 35.2) and have been responsible for the remarkable decline in the incidence of mumps and related sequelae.

Live, attenuated virus mumps vaccines were developed through continuous serial passage of wild-type isolates. At present, no clear distinguishing marker exists for attenuation of MuV strains apart from the failure of a passaged isolate to produce clinical symptoms in vaccinees, although various animal tests of mumps vaccine virulence are under evaluation. In the United States, the only licensed mumps vaccine is the Jeryl Lynn strain and currently is only available in combination with measles and rubella vaccines (MMR) or measles, rubella, and varicella vaccines (ProQuad [Merck, West Point, PA] in the United States). Monovalent Jeryl Lynn vaccine is no longer manufactured.

Because of demonstrated and theoretical considerations about spread of virus to placenta and fetal tissues, administration of vaccines containing live MuV three months before or during pregnancy is not advised.³⁰⁷

Prelicensure studies demonstrated that a single dose of the Jeryl Lynn vaccine strain induces protective levels of virus neutralizing antibodies in greater than 95% of recipients.^{165,359,412} Similar results have been found for other mumps vaccine strains licensed for use elsewhere.^{103,276} Although antibody titers after vaccination develop more slowly and are lower than those following natural infection, protection from natural mumps appears complete,^{45,110} and neutralizing antibody persists for decades.⁹⁴ However, waning and loss of neutralizing antibody has been reported as early as 4 years postvaccination.^{40,93,263}

The Jeryl Lynn vaccine is composed of two distinct but genetically related viruses, designated Jeryl Lynn-5 (JL-5) and Jeryl Lynn-2 (JL-2), existing in an approximate 5:1 ratio.⁶ These

two viruses differ from each other at 414 nucleotides (3%), leading to 87 amino acid substitutions.⁹ Over 500 million doses of the Jeryl Lynn–based MuV vaccines have been distributed worldwide, with few serious adverse effects noted.¹⁶⁴ Most reported complications (e.g., rash, pruritus, and purpura) have been allergic in nature; these complications are both uncommon and usually mild and self-limited.⁵⁵ Approaches for the immunization of egg-allergic children have been detailed.²²⁵ A comprehensive survey of the literature by the Vaccine Safety Committee of the Institute of Medicine failed to find adequate information to establish or reject a causal relationship between the administration of Jeryl Lynn MuV–containing vaccines and the development of encephalopathy, encephalitis, residual seizure disorders, optic neuritis, transverse myelitis, Guillain-Barré syndrome, IDDM, or sterility caused by orchitis, all of which have been extensively reviewed elsewhere.^{32,358} Parotitis following Jeryl Lynn vaccination occurs in approximately 1% of vaccinees.^{115,261,313}

Other widely distributed vaccine strains include the RIT 4385, Urabe AM9, Leningrad-Zagreb, and Rubini (discontinued). The RIT 4385 strain, produced by GlaxoSmithKline (Philadelphia, PA), was derived from the Jeryl Lynn strain by clonally isolating the JL-5 population.³⁷⁹ The Jeryl Lynn and RIT 4385 strains of vaccine appear to have similar safety and efficacy profiles.^{85,262,391}

In contrast to the Jeryl Lynn–based strains, most other strains have been linked to aseptic meningitis,^{72,171,200,206,247,274,285,386} occurring 15 to 21 days after vaccination, with a male predominance in those affected. The rate of vaccine-associated aseptic meningitis ranges from more than 1 case per 400 doses to less than 1 case per 100,000 doses, a range influenced by vaccine manufacturer, stringency of adverse event reporting, method of surveillance, study size, clinical definition, and background rates of aseptic meningitis.³⁴ The course of illness is mild, with no sequelae noted. Other, less frequent

adverse events following vaccination include orchitis^{2,73,217} and pancreatitis.^{113,381} Vaccine-associated sensorineural deafness has been reported but is exceedingly rare.¹⁵ Symptomatic transmission of certain vaccine viruses, including the Lenin-grad-3, Leningrad-Zagreb, and Urabe strains, has been reported.^{17,196,340} Although mumps and its complications are usually mild, most analyses of cost-to-benefit ratios favor an intensive vaccination program for developed nations.^{126,199,209,355,438}

The Rubini vaccine strain, which was extensively passaged in embryonated hens' eggs and WI-38 and MRC-5 human diploid cells,¹³⁴ was found to offer little protection against mumps.^{135,290,312,341} As of 2001, the World Health Organization (WHO) no longer recommended its use for national immunization programs.⁴²⁵

Vaccine Use

The Advisory Committee on Immunization Practices (ACIP) recommends administration of the first dose of MMR at 12 to 15 months of age and administration of a second dose at 4 to 6 years of age. The 1-dose schedule was instituted in 1977 and modified to a 2-dose schedule in 1989.⁵³ ProQuad (quadrivalent measles, mumps, rubella, and varicella vaccine) can be used in place of MMR for the second dose at any age, or for the first dose at 48 months of age or older.²⁴⁴ Studies suggest that vaccination as early as 9 months of age^{197,343} and a second dose at 9 to 13 years of age^{55,188,227} may be equally effective.

Vaccination in the face of recent chemotherapy or radiation therapy is unlikely to induce adequate serologic responses and should be delayed for at least 3 months following such treatment.³⁰⁷ Studies of MuV-containing vaccines in nonimmunocompromised HIV-infected patients, primarily in the form of trivalent mumps, measles, and rubella vaccines, have not documented serious or unusual adverse effects and therefore vaccination is recommended.^{60,252}

After many years of steadily declining disease incidence in the United States following the institution of mumps vaccination, a transient reversal in the number of reported cases of mumps occurred between 1986 and 1987 (Fig. 35.5). This appeared to be a reflection of the pool of susceptible children, teenagers, and young adults who were not immunized aggressively for mumps,^{39,65,74,163,199,355} especially during the first decade following introduction of the vaccine. Models of the effects of mass vaccination programs suggest that the average age of disease can be anticipated to rise with the level of induced immunity, with the additional paradoxical result of increased relative risk of serious consequences of mumps infection (e.g., orchitis in susceptible postpubertal males).¹⁰

Following the outbreaks in the late 1980s, the incidence of mumps rapidly returned to preoutbreak levels and then precipitously declined over the next two decades to record low levels before a resurgence in 2006 and then in 2009 (Fig. 35.5). In contrast to the 1986 and 1987 mumps outbreaks, most cases occurring in 2006 and 2009 involved persons with a history of 2 doses of vaccine.^{21,38,64,81,93,245,323,325} As discussed earlier, recent outbreaks appear to be facilitated by waning of vaccine-induced immune responses, which may be a consequence of the success of the mumps vaccination program itself in reducing wild-type virus circulation, resulting in reduced opportunities for periodic boosting, which in the past may have served to maintain immunity.⁹⁷

Measles is a highly contagious disease characterized by a prodromal illness of fever, coryza, cough, and conjunctivitis followed by the appearance of a generalized maculopapular rash. Introduction of measles into virgin populations and endemic transmission in populations with inadequate medical care are associated with high mortality. Despite the development of a successful live attenuated vaccine, measles remains a major cause of mortality in children, particularly in developing countries, and a cause of continuing outbreaks in industrialized nations.

HISTORY

Measles is a relatively new disease of humans and probably evolved from an animal morbillivirus. Phylogenetically, measles virus (MeV) is most closely related to rinderpest virus (RPV), a pathogen of cattle (Fig. 36.1), and it is postulated that MeV evolved in an environment where cattle and humans lived in

close proximity.⁴⁴⁴ Because large numbers of people are required to generate sufficient susceptible individuals to maintain measles in a population, measles may have evolved in the early centers of civilization in the Middle East where populations attained sufficient densities to sustain continued transmission.⁴⁴⁴

Abu Becr, an Arab physician known as Rhazes of Baghdad, is generally credited with distinguishing smallpox from measles in the 9th century. He dated its first description to the 6th century. Rhazes referred to measles as *hasbah* (eruption) and regarded it as a modification of smallpox with the distinction that “anxiety of mind, sick qualms and heaviness of heart oppress more in the measles than in the smallpox”.⁵⁸⁵ Repeated epidemics of illnesses characterized by a rash are recorded in European and Far Eastern populations between 1 and 1200 AD.⁴⁴⁴ It appears that measles spread across the Pyrenees into France with the Saracen invasion of the 8th century.⁶⁰⁰ Repeated epidemics identified as measles were recorded in the 11th and 12th centuries, and it is first mentioned as a childhood disease in 1224.⁴⁴⁴

In the European literature the name applied was “morbili,” derived from the Italian “little diseases” to distinguish it from plague, “il morbo,” but morbili included several exanthemata. Sanvages in 1763 defined morbili as measles but called it rubeola (derived from the Spanish⁶⁰⁰), leading to a common confusion with rubella that persists to the present. Introduction of measles into previously unexposed populations has been associated with high morbidity and mortality.^{68,600,655,667} Epidemics of rash illnesses were associated with episodes of depopulation in China, India, and the Mediterranean region. Introduction of measles into the Fiji Islands in 1875 resulted in 26% mortality.⁶⁰⁰ Approximately 56 million people died as a result of European exploration of the New World, largely due to the introduction into native Amerindian populations of Old World diseases, notably smallpox and measles. Decreases in population are likely to have facilitated the transfer of Spanish culture to South America.⁴⁴⁴

Many of the basic principles of measles epidemiology were elucidated by Peter Panum, a Danish physician who worked in the Faroe Islands during a large measles epidemic in 1846.⁵³⁰ Panum deduced the highly contagious nature of the disease, the 14-day incubation period, and the lifelong immunity present in older residents and postulated a respiratory route of transmission.

Complications of measles were first described in the 18th century. In 1790, James Lucas, an English surgeon, described the first case of postmeasles encephalomyelitis in a young woman who developed paraparesis as the rash was fading.⁴¹² Nineteenth-century medical textbooks associated measles with the exacerbation of tuberculosis, and in 1908, while working at a tuberculosis hospital in Vienna, von Pirquet recorded the disappearance of

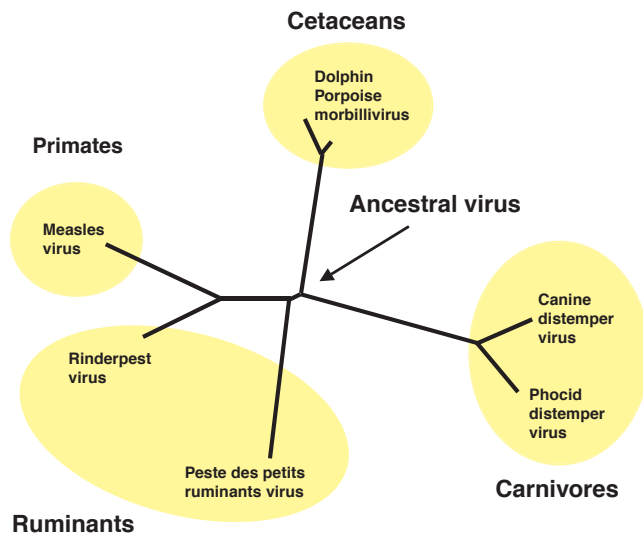

FIGURE 36.1. Genetic relationships between morbilliviruses based on comparison of the nucleotide sequences of the N genes. The tree was derived using PHILIP, DNADIST, and FITCH programs. The branch lengths are proportional to the mutational differences between the viruses and the hypothetical common ancestor that existed at the nodes in the tree. (From Barrett T. Morbillivirus infections, with special emphasis on morbilliviruses of carnivores. *Vet Microbiol* 1999;69:3–13, with permission.)

delayed-type hypersensitivity skin test responses to tuberculin,⁷⁵⁰ the first experimental evidence of measles-induced immune suppression.

In 1933, Dawson described subacute sclerosing panencephalitis (SSPE) in a 16-year-old boy with progressive neurologic deterioration. Histologic examination of the brain showed eosinophilic intranuclear and intracytoplasmic inclusions in neurons and glial cells.¹⁴² After reports of paramyxovirus-like particles in the inclusions,⁷¹⁷ observations of elevated levels of MeV antibody in serum and cerebrospinal fluid (CSF) and the reactivity of the inclusions with antibody to MeV identified the paramyxovirus as MeV.¹³⁰

INFECTIOUS AGENT

In 1757, an infectious agent was formally shown to be the cause of measles when the Scottish physician Francis Home, attempting immunization, transmitted the disease to naive individuals using blood taken from measles patients during the early stages of the rash.²⁹⁷ In 1905, Hektoen transmitted disease to volunteers with blood “free of bacteria” taken from measles cases in the acute stage and observed an incubation period of 13 days.²⁸⁰ In 1911, Goldberger and Anderson transmitted measles to rhesus macaques with filtered respiratory tract secretions from measles patients and successfully passed disease from one monkey to another.^{238,531}

Propagation and Assay in Cell Culture

Primary Isolation

In 1954, Enders and Peebles first isolated MeV in tissue culture by inoculating primary human kidney cells with the blood

of David Edmonston, a child with measles.¹⁸⁴ Isolates were also made using primary monkey kidney cells¹⁸⁴ and later continuous monkey kidney cell lines (e.g., Vero, CV-1).⁶⁷⁷ However, isolation of wild-type strains of MeV is most often successful using an Epstein-Barr virus-transformed marmoset B-lymphocyte line, B95-8³⁶⁵; a human T-cell line from cord blood, COBL-a³⁶⁴; or Vero cells engineered to express the MeV receptor signaling lymphocyte activation molecule (SLAM).⁵²¹ Generally, the first observable sign of virus growth is cell–cell fusion and syncytia formation (Fig. 36.2).

Laboratory Propagation and Assay

Growth of MeV led to the development of live-attenuated vaccine strains by adaptation of MeV to growth in cells from foreign hosts, such as the chick embryo and canine and bovine kidney cells.³⁴⁹ Most experimental work is done with tissue culture–adapted strains so virus stocks are generally grown in Vero cells using a low multiplicity of infection to avoid accumulation of defective interfering (DI) particles. Vero and Vero/SLAM cells are useful for virus titration by plaque formation.¹⁰ The virus replicates slowly and 3 to 5 days of culture are often needed for plaques to become visible. Wild-type strains can also be assayed by syncytia formation in B95-8 or human cord blood mononuclear cells.

Biological Characteristics

The morbilliviruses form two genetically distinct groups of viruses related either to canine distemper virus (CDV) or to RPV (Fig. 36.1)⁵⁰ and differ from other paramyxoviruses in formation of intranuclear inclusion bodies. Virions are pleomorphic and range in size from 100 to 300 nm. The envelope carries surface projections that are composed of the viral transmembrane hemagglutinin (H) and fusion (F) glycoproteins (Fig. 36.3). The matrix (M) protein lines the interior of the virion envelope. The helical ribonucleocapsid (total length of 1.2 μm) formed from the 16 kb genomic RNA wrapped with the nucleocapsid (N) protein is packed within the envelope in the form of a symmetrical coil with the phosphoprotein (P) and large polymerase (L) proteins attached.

Proteins

NUCLEOCAPSID PROTEIN

The N protein messenger RNA (mRNA) is the first transcribed from the genome and the N protein (525 amino acids [aa]) is the most abundant of the viral proteins. N appears as a 60-kD band on polyacrylamide gels and can self-assemble but usually surrounds viral genomic or antigenomic RNAs to form helical ribonucleocapsid structures.¹⁰⁰ This conformationally flexible structure^{62,643} is the required template for both replication and transcription. Each N monomer binds six nucleotides, and viral genomes must be multiples of six for replication.³⁶⁷ Monomeric N (N^0) can be transported into the nucleus but is usually retained in the cytoplasm by binding to P.^{309,679} Phosphorylation regulates oligomer formation and activation of transcription.^{243,267}

N is organized into two functionally distinct regions. The N-terminal portion of the protein (aa 1 to 400, N_{CORE}) is conserved and is required for self-assembly into nucleocapsids and for RNA binding^{44,242,342,403,679} (Fig. 36.4). N_{CORE} forms a globular domain located toward the helical axis of the nucleocapsid,⁶⁴³ includes a nuclear localization signal,⁶²⁸ and

FIGURE 36.2. Typical cytopathic effects of syncytia formation associated with measles virus (MeV) replication in Vero cells. A: Unstained cells in culture. (A courtesy of William Bellini, Centers for Disease Control and Prevention, Atlanta, Georgia.) **B:** Cells stained with a fluorescently labeled antibody to MeV.

can also react with the cell surface through FcγRII.⁵⁷⁹ The C-terminal portion of the protein (aa 401 to 525, N_{TAIL}) is more variable, intrinsically disordered, acidic, and phosphorylated.^{40,110,267,341,408,567} N interacts with P through residues in N_{CORE} and N_{TAIL}.^{44,77,356,792} N_{TAIL} is required for nucleocapsid

flexibility,⁶² but its location in the nucleocapsid structure is not clear.¹⁵¹ N_{TAIL} contains an α-helical molecular recognition element (α-MoRE, aa 488 to 499) reversibly involved in induced α-helical folding upon interaction with the X domain (XD) in the C-terminus of P (PCT) that likely positions the polymerase

FIGURE 36.3. Schematic diagram of measles virus. The lipid bilayer of the pleomorphic particle is represented by blue lines, under which the matrix protein layer (red) resides. The viral membrane is densely packed with envelope glycoprotein complexes consisting of fusion protein trimers (shades of blue) and attachment protein tetramers (shades of green). The negative-strand RNA genome and the nucleocapsid protein (orange) form the nucleocapsid, which interacts with the phosphoprotein (light blue) and the polymerase (purple). In addition to contacts between the nucleocapsid and matrix proteins,³²⁵ the luminal tails of the glycoproteins are thought to contact the matrix layer. Individual viral components are not drawn to scale. Structural renderings of the glycoprotein complexes are based on original crystal structures (H head domains²⁷⁷); homology models of measles virus (MeV) F^{386,552} derived from coordinates reported for pre- and postfusion PIV5 and PIV3 F, respectively^{794,795}; or hypothetical structural models (F prehairpin intermediate). High-resolution structural models were aligned at the level of the transmembrane domain (viral envelope) as described⁵²⁷ and then morphed into low-resolution images using the Sculptor (resolution 12, voxel size 3) package.⁵⁴ (Adapted from Plemper RK, Brindley MA, Iorio RM. Structural and mechanistic studies of measles virus illuminate paramyxovirus entry. *PLoS Pathog* 2011;7:e1002058; courtesy of M. A. Brindley and R. K. Plemper.)

FIGURE 36.4. Schematic diagram of the nucleocapsid (N) protein. The N-terminal region (N_{CORE}) contains the RNA-binding domain and the oligomerization domain and is sufficient for nucleocapsid formation. The C-terminal region (N_{TAIL}) is unstructured and acidic, binds C-terminal domain of P (PCT), and contains the region of sequence variability that is used for identification of measles virus (MeV) clades. Regions of interaction with N and P are indicated.

complex near the RNA in the nucleocapsid.^{44,76,77,151,333,408,468} The intrinsic disorder of N_{TAIL} provides a structural plasticity that allows strain- and cell type-specific interactions with several host proteins including heat shock protein (Hsp) 72, interferon regulatory factor (IRF)-3, the cellular protein responsible for nuclear export of N, the p40 subunit of eukaryotic initiation factor 3, cyclophilins A and B, and an unidentified cell surface nucleocapsid receptor.^{128,379,627,718,760,803}

P, C AND V PROTEINS

The P (phospho) protein (507 aa) is a polymerase co-factor that is activated by phosphorylation, forms tetramers, and links L to N to form the replicase complex.¹³⁵ While the 72-kD P protein is abundant in the infected cell, only small amounts are present in the packaged virus. P is a multifunctional protein with a modular organization (Fig. 36.5). The N-terminus (PNT) is poorly conserved, intrinsically unstructured, acidic, phosphorylated, and required for replication. PNT binds to N_{CORE} and this interaction induces folding of PNT.³⁴³ PNT is a chaperone for N^0 that prevents binding to cellular RNAs, illegitimate N self-assembly, and nuclear translocation. PNT initiates encapsidation of genomic viral RNA by sequence-specific binding of the leader RNA.^{135,309} Elongation of the nucleocapsid structure is sequence independent. PNT also interacts with cellular proteins to regulate the response to interferon (IFN) (see discussion of V later).

FIGURE 36.5. Schematic diagram of the phospho (P), C, and V proteins. Diagram of the proteins encoded in the P gene. P and C are initiated at AUGs in different reading frames. The N-terminal region of P (PNT) is acidic, unstructured, and phosphorylated on serines and binds N^0 . The C-terminal region of P (PCT) has the P oligomerization domain and the X domain that binds and induces folding of N_{TAIL} . V is translated from an edited RNA with a nontemplated G at nucleotide 751 that results in a distinct cysteine-rich zinc-binding C-terminus.

PCT is conserved⁴⁵ and contains all domains required for transcription. The region between amino acids 204 and 321 contains the α -helical domain that binds to N_{TAIL} as part of the nucleocapsid structure and is responsible for tethering the polymerase L to its template.^{309,356} A coiled-coil domain between aa 344 to 411 is sufficient for P oligomerization.¹³⁵ The unique XD portion of PCT (aa 459 to 507) has three α -helices arranged in an antiparallel triple helix bundle that binds the N_{TAIL} α -MoRE with 1:1 stoichiometry and induces its folding.^{65,229,336,356,408} Binding affinity is weak, consistent with a model in which XD is responsible for tethering L to the ribonucleocapsid in a way that allows it to progress during RNA synthesis.^{356,792} XD also interacts with and stabilizes the ubiquitin ligase p53-induced-RING-H2.¹¹⁸

The P gene of MeV, like other members of the *Paramyxoviridae*, encodes proteins in addition to P that, together with P, regulate the innate response to infection (Fig. 36.5). The C protein is a basic protein of 186 amino acids encoded by the same mRNA but translated using an initiator methionine codon 19 nucleotides downstream from that for P and an overlapping reading frame.⁶⁰ The V protein shares the initiator methionine and the amino terminal 231 amino acids of the P protein, but RNA editing adds an extra non-template-directed guanosine (G) residue at position 751. This shifts the reading frame and results in a different 68-amino acid cysteine-rich C-terminus with zinc-binding properties.^{105,404} Neither C nor V is necessary for MeV replication in Vero cells,^{572,636} but both C and V interact with cellular proteins and regulate the response to infection.^{155,405,646,722}

C interferes with innate immune responses by inhibition of IFN signaling, modulates viral polymerase activity, and has been implicated in prevention of cell death.^{47,584,654,711} Deletion of C decreases MeV replication in monkeys, peripheral blood mononuclear cells (PBMCs), and thymic epithelial cells and decreases neurovirulence for CD46 transgenic mice, suggesting that C has an important *in vivo* role.^{155,194,537,711,731} In some cells decreased replication is associated with inhibition of translation and induction of IFN.⁴⁹¹ C suppresses IFN induction by regulating viral RNA synthesis⁴⁹⁰ and preventing the activation of the cellular protein kinase PKR.^{435,723}

MATRIX (M) PROTEIN

The envelope of the virion (Fig. 36.3) consists of the M protein (335 aa) and the two transmembrane glycoproteins F and H. M is a basic protein with several conserved hydrophobic domains.⁵⁹ The mRNAs for morbillivirus M proteins contain approximately 400 nucleotides of noncoding sequence at the 3'

end that increases M protein production.^{59,705} In infected cells M is associated with nucleocapsids and with detergent-resistant regions of the inner layer of the plasma membrane where it regulates MeV RNA synthesis and assembly.^{291,325,556} M also interacts with the intracytoplasmic regions of one or both transmembrane glycoproteins, modulates the targeting and fusogenic capacity of the envelope glycoproteins, and directs release of virus from the apical surface of polarized epithelial cells.^{71,487,556,618} Deletion of M increases cell-to-cell fusion and decreases production of infectious virus.¹⁰² These properties are often defective in the mutated M proteins of viruses causing persistent infection.^{290,693}

FUSION (F) PROTEIN

F is a highly conserved type I transmembrane glycoprotein synthesized as an inactive precursor (F₀) of about 60 kD. The mRNAs for morbillivirus F₀ proteins contain unusually long (460 to 585 nucleotides) G-C rich 5' nontranslated regions (NTRs) that are predicted to have extensive secondary structure and are followed by clusters of three to four AUGs.⁵⁸⁸ The 5' NTR influences the choice of AUG and decreases translation of F, virus production, and cytopathogenicity.^{101,705} There is a 28-residue signal sequence and after translation, F is glycosylated and trimerized in the endoplasmic reticulum (ER).⁵⁵⁰ F₀ is cleaved at a multibasic site (108 to 112: Arg-Arg-His-Lys-Arg) by furin in the trans-Golgi to yield the 41-kD (F₁) and 18-kD (F₂) disulfide-linked fusion-competent mature protein.^{73,761} Mutation of Arg 112 results in a reduced rate of F transport to the cell surface, aberrant cleavage, and abolition of the fusogenic activity necessary for infection.^{13,761} Restricted processing of F is associated with persistent infection.⁴⁴⁷ The 33-residue cytoplasmic tail of F₁ possesses basolateral sorting

and endocytosis signals.⁴⁶¹ F₂ has all of the predicted N-linked glycosylation sites (aa 29, 61, and 67). Mutation of any of these asparagines decreases transport to the cell surface and impairs proteolytic cleavage, stability, and the fusion capacity of F, perhaps because F₂ is an integral part of the prefusion F head.^{14,746}

F₁ contains a highly conserved stretch of hydrophobic amino acid residues at the new N-terminus (aa 113 to 145) that constitutes the fusion peptide. Oligopeptides that mimic this segment of F₁ inhibit fusion.⁵⁸⁷ Mutants resistant to the fusion inhibitory effect of these oligopeptides have amino acid alterations in a cysteine-rich region (aa 337 to 381) of F₁ important for interaction with H³¹¹ (Fig. 36.6). There are two predicted heptad repeat amphipathic α -helices: one adjacent to the fusion peptide and another N-terminal to the transmembrane region. Partial membrane-proximal cleavage between the heptad repeat and the transmembrane region enhances fusion.⁷⁴⁸ Synthetic peptides representing the heptad repeat regions inhibit fusion,³⁸¹ as does mutagenesis of the leucines in the zipper region.⁸³ F₂ possesses a third heptad repeat region that modulates fusogenicity through a microdomain around residue 94.⁵⁴⁸

Fusion requires the expression of both H and F, with a predicted interaction of the F head with the H stalk (Fig. 36.6), and binding of H to a cell surface receptor (Fig. 36.7).^{385,527,802} Modeling of pre- and postfusion conformations of the F trimer indicates large conformational changes that result in formation of a six-helical bundle.⁵⁶⁸ Basolateral expression of H and F is important for syncytia formation and increases cell-to-cell spread *in vitro* and *in vivo*.⁴⁶¹ In polarized epithelial cells transport is directed by interaction of the F luminal tail with M to the apical surface where virus is released.^{71,487} F tail mutations in viruses causing persistent infection include premature stop codons, missense mutations, altered reading frames, and

FIGURE 36.6. Schematic of measles virus (MeV) membrane fusion. MeV H and F envelope glycoproteins exist as hetero-oligomeric complexes on the surface of infectious viral particles (**left panel**). Receptor binding by the H protein triggers major conformational changes in prefusion F, resulting in insertion of the F fusion peptide domain into the target membrane in a hypothetical prehairpin intermediate conformation (**center**). Most likely, the concerted refolding of several prehairpin F complexes into the thermodynamically stable postfusion conformation is required to open a fusion pore and enable infection (**right panel**). For clarity, MeV H is represented as a single tetramer and F as a single trimer in the hetero-oligomeric fusion complex. More than one F trimer may interact with each individual H tetramer. The **insert** shows enlarged representations of hypothetical lipid mixing intermediates. Formation of a local fusion nipple is thought to be followed by merger of the outer lipid layers (lipid stalk; hemifusion stage) and ultimately merger of the inner lipid layers and the opening of a fusion pore. F complexes have been eliminated from the lipid mixing representation. Structural renderings were prepared as described in Figure 36.3. (Adapted from Plemper RK, Brindley MA, Iorio RM. Structural and mechanistic studies of measles virus illuminate paramyxovirus entry. *PLoS Pathog* 2011;7:e1002058; courtesy of M. A. Brindley and R. K. Plemper.)

FIGURE 36.7. Crystal structures of the measles virus hemagglutinin (MeV-H) in complex with its receptors. **A:** The H head domain (monomer) unbound (**left**) and bound to signaling lymphocyte activation molecule (SLAM) (**middle**) or CD46 (**right**). The H head domain as viewed downward from top is illustrated as a cartoon model. It exhibits the six-bladed β -propeller fold ($\beta 1$ through $\beta 6$, rainbow colors). This structure is topologically similar to the hemagglutinin neuraminidase of other paramyxoviruses and the influenza virus neuraminidase. The SLAM V domain (cyan) and CD46 SCR1 and 2 domains (pink) are shown in surface models. **B:** Two forms of H tetramer (dimer of dimers) with each monomer bound to the SLAM V domain as observed in the crystals of the H-SLAM complex. H monomers A (violet) and B (light pink) form one dimer, while monomers C (dark gray) and D (light gray) form another. Each dimer (AB or CD) constituting a tetramer has essentially the same structure within and between the two forms and is likely the basic unit of MeV-H. In Form I (**left**), monomers A and C largely form the interface of two dimers, whereas in Form II (**right**), monomers B and D do so. SLAM is shown in cyan. PDB ID: MV-H receptor free form (2ZB6), MV-H-SLAM Form I (3ALZ) and Form II (3ALX), MV-H-CD46 (3INB). (Courtesy of Takao Tashiguchi, Katsumi Maenaka, and Yusuke Yanagi.)

nonconservative amino acid substitutions.^{104,635} These changes interfere with virus envelope assembly and budding and increase cell-to-cell fusion and neurovirulence in hamsters.^{36,103}

HEMAGGLUTININ (H) PROTEIN

H (617 aa) is the receptor-binding and hemagglutinating (HA) protein and an important determinant of morbillivirus cellular tropism. H is a type II transmembrane glycoprotein that resides on the surfaces of infected cells and virions as disulfide-linked homodimers that associate in the ER to form tetramers (Figs. 36.3 and 36.7).^{79,277,550} The mature H protein has a cytoplasmic tail of 34 amino acids preceding a single hydrophobic transmembrane region and a large C-terminal ectodomain with 13 strongly conserved cysteines. The cytoplasmic tail is essential for efficient transport to the cell surface and includes signals for basolateral sorting and endocytosis. However, H can be redirected to the apical surface for efficient particle formation and virus release.^{71,462,463}

The H protein of the Edmonston strain of MeV has five predicted N-linked glycosylation sites clustered between positions 168 and 238 (Fig. 36.8). The first four of these sites are used.³⁰⁵ More recent MeV isolates often have an additional glycosylation site at residue 416, and this correlates with a loss of HA activity.⁶¹⁵ Glycosylation is necessary for proper folding, antigenicity, dimerization, and export of H from the Golgi.³⁰⁵ H processing and intracellular transport is relatively slow, taking approximately 30 minutes for oligomerization and an hour to reach the medial Golgi.³⁰⁶ During persistent infections H proteins often accumulate mutations that affect glycosylation, oligomerization, and intracellular transport.¹⁰⁴

Structural studies of H indicate that the N-terminus forms an α -helical stalk supporting a cubic-shaped six-blade β -propeller head structure (Fig. 36.7).^{127,276,385} Each of the blade modules contains four antiparallel β -strands connected sequentially through extended loops. In the dimer, N-linked carbohydrates cover the top pocket of the head domain and

FIGURE 36.8. Structural relationships between glycans, antibody epitopes, and receptor binding sites on the hemagglutinin protein. Measles virus hemagglutinin (MeV-H) dimer (blue white) as viewed downward from top is illustrated as surface presentation with plausible N-linked sugars (black), which cover large surface areas of H. Epitopes for anti-H monoclonal antibodies (magenta) are mapped onto the sugar-uncovered surface of H (A). This area also includes binding sites for signaling lymphocyte activation molecule (SLAM) (cyan, B), nectin 4 (red, C), and CD46 (pink, D). Because the structure of the H-nectin 4 complex has not been determined, the putative binding sites for nectin 4 are indicated, based on mutagenesis analysis. Most neutralizing antibodies bind to sites that overlap or are located very close to the receptor binding sites, which are unlikely to mutate. This may explain why measles virus has never escaped immune responses induced by natural infection or vaccination and why there is only a single serotype. PDB ID: MV-H receptor free form (2ZB6), MV-H-SLAM (3ALX), MV-H-CD46 (3INB). (Courtesy of Takao Tashiguchi, Katsumi Maenaka, and Yusuke Yanagi.)

cause the two molecules to tilt away from each other, optimizing exposure of neutralizing epitopes and the receptor-binding sites away from the dimer interface on the lateral surface (Fig. 36.8)^{276,308,749,751} (see section on Cellular Receptors). Cysteine residues at 139 and 154 are responsible for intermolecular disulfide bonding of monomeric H glycoproteins.⁵⁴⁹

H acts in conjunction with F for budding and for cell-to-cell fusion and entry (Fig. 36.6). Fusion occurs through conformational changes in both proteins triggered by the binding of H to a cellular receptor (Fig. 36.7).^{277,321,499,500,624} Heterooligomerization occurs in the ER.⁵⁵⁰ Mutagenesis has identified separate regions in the H stalk required for interacting with F and for triggering F fusion.^{385,527,547} MeV fusogenicity correlates inversely with the strength of the interaction between F and H^{133,134,189,321,551} (see section on Entry).

L PROTEIN

The L (large) protein (2,183 aa) is a multidomain protein with several highly conserved regions. One contains the Gly-Asp-Asn-Gln motif common to the RNA polymerases of negative-strand viruses.^{174,669} L is present in small quantities in the infected cell, interacts with and functions in association with P, and is part of the viral nucleocapsid both in the cell and in the virion. A domain in the N-terminal 408 amino acids binds to a trihelical binding domain in PCT that links it to the nucleocapsid for transcription and replication.^{300,357}

Cellular Receptors

MeV can infect several types of cells and uses multiple receptors in a virus strain and cell type-specific manner. Three of these receptors have been identified: membrane co-factor protein or CD46,^{168,497} SLAM or CD150,⁷¹⁵ and polio virus receptor-related 4 (PVRL4) or nectin 4.^{479,508} The binding sites for these cellular receptors are all found on the lateral surface of the head structure of H^{277,622} (Figs. 36.7 and 36.8).

CD46

CD46 is a widely distributed human complement regulatory protein expressed on all nucleated cells and preferentially on

the apical surface of polarized epithelial cells.^{71,445} It normally acts as a co-factor in the proteolytic inactivation of C3b/C4b by factor I.⁵⁹¹ Monkeys have a CD46 homolog that is expressed on erythrocytes, but such a protein has not been identified in mice. Multiple mRNAs are produced by alternative splicing of CD46 transcripts. All code for proteins that contain an N-terminal signal peptide, four short consensus repeats (SCRs), a transmembrane region, and an anchor. Isoforms differ in the length and composition of an extracellular serine/threonine/proline domain near the transmembrane segment and in having one of two alternative cytoplasmic tails.⁵⁹¹ The cytoplasmic tail of CD46 is associated with intracellular kinases and adaptor proteins, and cross-linking of CD46 can induce autophagy and regulate inflammatory responses.^{338,591} The four isoforms common on human cells can all serve as receptors for MeV.^{231,423} SCR1 and SCR2 interact with the MeV H protein, while SCRs 2, 3, and 4 bind C3b/C4b.⁵⁹¹ MeV infection of cells or expression of the H protein alone can lead to rapid internalization of CD46 from the cell surface.³⁷³ In persistently infected cells CD46 down-regulation is accomplished through a membrane-proximal Tyr-X-X-Leu motif in the cytoplasmic domain.⁷⁹¹

The H binding site involves one planar face of SCR1 and SCR2 with an important role for the N-linked carbohydrates on SCR2.^{99,304,417} Most vaccine strains use CD46 efficiently, while wild-type strains often do not.^{191,790} A tyrosine at position 481 of H and glycine at 546 are key determinants of the affinity of H for CD46,^{53,660} but several additional residues are also important.^{432,603,637,695} The crystal structure of Edmonston H with SCR1 and SCR2 shows that CD46 binds to the side of the β -propeller through three contact regions on blades 4 and 5 (Figs. 36.7 and 36.8).⁶²²

SLAM

SLAM/CD150 is a 70-kD glycoprotein expressed on cells of the immune system including immature thymocytes, activated T and B lymphocytes, activated monocytes, and mature dendritic cells.¹²⁴ SLAM is a member of a family of immunomodulatory type I transmembrane proteins^{93,153} and is the most important receptor for MeV infection of lymphoid tissue.¹⁴³

A recombinant MeV that interacts inefficiently with SLAM is attenuated in macaques.³⁸⁹ CDV, RPV, and peste des petits ruminants virus also use SLAM as a receptor, suggesting that this is a common feature of morbilliviruses.^{5,49,716,749}

SLAM has two highly glycosylated immunoglobulin-like domains (V and C2) and structural features of the CD2 family of membrane proteins.^{670,790} The cytoplasmic domain has immunoreceptor tyrosine-based switch motifs that bind small SH2 (src homology 2) domain adaptor proteins, such as SLAM-associated protein (SAP) and Ewing sarcoma-associated transcript-2 (EAT-2), important for cell signaling.^{93,153,515,670,790} MeV H binds to the V domain of human, but not mouse, SLAM,⁵¹⁵ and this results in down-regulation of SLAM expression on the surface of infected cells.⁷⁶⁷ Mutagenesis studies have identified MeV H residues Ile194, Asp505, Asp507, Asp530, Arg533, Phe552, and Pro554 as important for binding SLAM.^{431,500,751} The crystal structure of H with the V domain of SLAM shows that these residues contribute to four components of the binding interface located primarily on the side of H blade 5 contiguous to the binding site for CD46²⁷⁷ (Fig. 36.7).

Studies of different strains of MeV have shown that both vaccine and wild-type strains can use SLAM as a receptor and that most H proteins can bind both CD46 and SLAM, but receptor affinity and efficiency of entry differ.^{191,422,432,521,621,637,751,790} In general, binding to SLAM is of higher affinity than binding to CD46.⁴³² Viruses with asparagine at H481 use SLAM and enter PBMCs more efficiently than viruses with tyrosine at this position.^{191,637} Differences in efficient receptor usage likely involve interactions with MeV proteins in addition to H.^{370,710}

NECTIN 4

The distributions of SLAM and CD46 in tissues do not account for MeV replication in epithelial cells *in vivo* or *in vitro*.^{18,197,278,460,519,661,696,708–710} Recently, poliovirus receptor-like 4/nectin 4, an adherens junction protein of the immunoglobulin superfamily, has been identified as a receptor on epithelial cells.^{479,508} This is consistent with previous studies that indicated that an epithelial receptor is expressed on the basolateral surface of polarized cells and involved in formation of tight junctions.^{665,674} Nectin 4 is a transmembrane protein with two C2-type immunoglobulin domains and a V domain that interacts with H.⁴⁷⁹

OTHER RECEPTORS

Several pieces of information suggest that MeV uses additional receptors. The currently known receptors do not account for the ability of MeV to infect endothelial cells in acute infections¹⁹⁷ or cells of the central nervous system in chronic infections.^{445,661} Receptors used by attenuated vaccine strains adapted to growth in cells from nonsusceptible hosts (e.g., chickens) probably represent an additional category of MeV receptors that have yet to be identified.¹⁹³

Other cell surface molecules interact with MeV but do not serve as entry receptors. For instance, MeV H can bind Toll-like receptor 2 (TLR2) and induce signaling.⁶³ Dendritic cell-specific intercellular adhesion molecule 3 (ICAM-3) grabbing nonintegrin (DC-SIGN) is an attachment receptor that enhances infection and modulates function of DCs.^{31,147,263} Incorporation of cyclophilin B into MeV virions by binding to N leads to interaction with the cyclophilin ligand CD147/EMMPRIN, a multifunctional transmembrane protein expressed on epithelial and neural cells.⁷⁶⁰

Hemagglutination, Hemadsorption, and Hemolysis

Some strains of MeV bind to and agglutinate the erythrocytes of Old World monkeys, particularly African green, patas, and rhesus macaques. HA occurs optimally at physiologic pH and 37°C. Infected cells can also adsorb monkey erythrocytes (hemadsorption). Both HA and hemadsorption are properties of the H glycoprotein. Many wild-type MeV isolates require high salt or have little HA activity.⁵⁹⁴ HA of monkey erythrocytes is indicative of binding to CD46, is improved by adaptation to growth in Vero cells, and is dependent on the C-terminal 18 amino acids of H, amino acids 451 and 481, and absence of glycosylation at 416.^{616,630,660} This is consistent with the distribution of the CD46 molecule, which is not present on human red blood cells, and with the molecular characteristics of primate CD46.³⁰³ In baboons, lack of HA is due to an amino acid substitution in SCR2 and in New World monkeys to an absence of SCR1.³⁰³ HA is followed within a few hours by lysis of the agglutinated erythrocytes. Hemolysis is a consequence of fusion and dependent on F, as well as H.^{14,108,779}

Entry

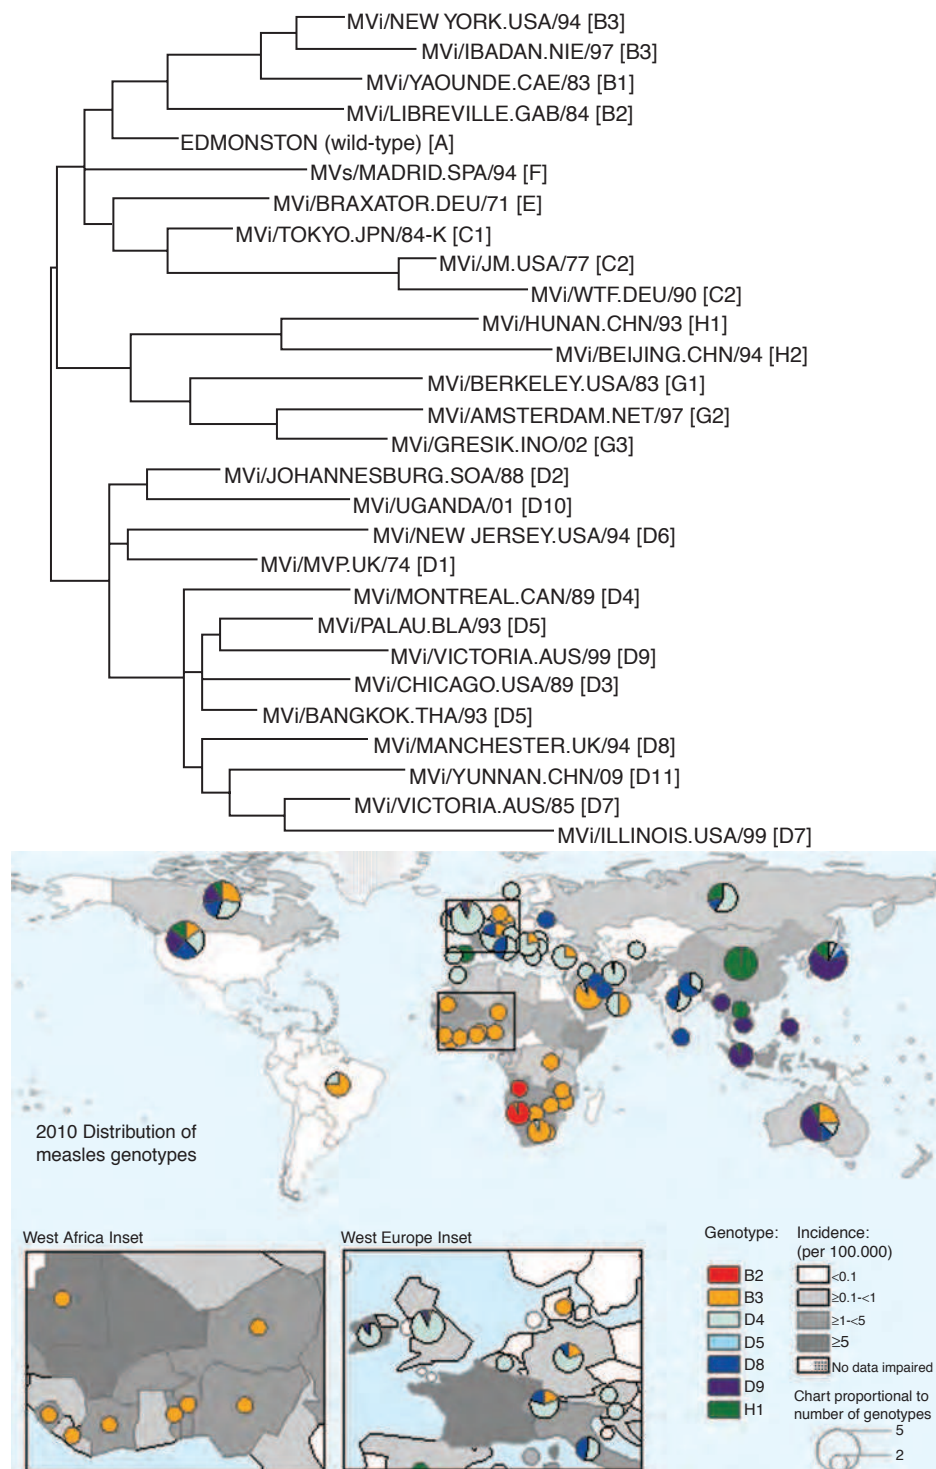

H attachment to a cellular receptor is followed by fusion of the virus envelope with the plasma membrane and delivery of the viral ribonucleocapsid into the cytoplasm for initiation of infection (Fig. 36.6). The H dimer of dimers (tetramer) associates with the prefusion F trimer in the secretory system of the host cell and exists as H-F hetero-oligomer on the virion surface (Fig. 36.3). The oligomers cooperate to induce fusion at neutral pH.⁵¹⁶ Fusion requires H and F to be from compatible virus species and prior cleavage of F₀ into F₁ and F₂.⁴⁷⁸ The MeV H protein stalk interacts directly with the MeV F protein head, suggesting that the metastable F trimer is shorter than the H tetramer, resulting in a staggered head domain arrangement on the virion surface (Figs. 36.3 and 36.6).^{385,527,547} The strength of H and F binding determines fusogenicity. More avid binding decreases fusion, indicating the need for H and F dissociation during the process of entry and productive infection.¹⁸⁹ Separate regions on the H stalk have been identified for F interaction and for F triggering, suggesting that these are discrete functions.^{79,547} It is postulated that interaction of H with its receptor on the cell membrane induces a reorganization of the dimer-dimer head domains that transmit receptor binding to the F contact zone in the H stalk to trigger refolding of F and membrane fusion.^{277,499,624} This H reorganization may be represented in the crystal structure of H with SLAM that shows two forms of the H dimer with the orientation shifted with respect to each other^{277,547} (Fig. 36.7).

Cytopathic Effects

MeV replication in cell culture results in cytopathic changes of three varieties: multinucleated giant cells (syncytia), altered cell shape, and inclusion bodies.¹⁸⁵ Cell-to-cell fusion occurs at neutral pH and syncytia formation occurs *in vitro* (Fig. 36.2) and *in vivo*¹⁸⁴ presumably using fusion mechanisms similar to those for virus entry (Fig. 36.6). Syncytia formation is facilitated by basolateral expression of H and F and the actin filament-plasma membrane cross-linker moesin and is inhibited by cytochalasin B.¹⁶⁷ Fusion of infected cells with uninfected cells may produce syncytia with 50 or more nuclei. Nuclei in the center of the syncytia have marginated chromatin¹⁸⁴ and are often undergoing apoptotic cell death¹⁹⁶ leading to plaque

FIGURE 36.9. Genetic variation in wild-type measles viruses (MeV) and geographic distribution of MeV genotypes. The World Health Organization (WHO) currently recognizes 23 genotypes and one provisional genotype of wild-type MeV. The phylogenetic tree (top) is based on the sequences of the N genes of the WHO reference strains for each genotype⁷⁷⁵ and the provisional genotype.⁸⁰⁴

Map (bottom) shows the global distribution of MeV genotypes and measles incidence in 2010. Colored circles indicate MeV genotypes reported to the WHO database for the year 2010, and the size of the circles is proportional to the number of genotypes reported for the indicated areas. Two areas, Western Africa and Eastern Europe, are also shown as inserts to provide more resolution. The boundaries and names shown and the designations used on this map do not imply the expression of any opinion whatsoever on the part of the WHO concerning the legal status of any country, territory, city, or area or of its authorities, or concerning the delimitation of its frontiers of boundaries. (Courtesy of David Featherstone, WHO, and Paul Rota, Centers for Disease Control and Prevention.)

formation *in vitro*. Infected cells may also change from a normal polygonal shape to a stellate, dendritic, or spindle shape with increased refractility to light. This type of “strand-forming” cytopathic effect appears after several passages and may be related to the production of DI particles.⁴⁴³

Both spindle-shaped cells and syncytial cells may contain intracytoplasmic and intranuclear inclusion bodies. Cytoplasmic inclusions are generally larger than nuclear inclusions and contain N-encapsidated RNA decorated with P, producing *fuzzy* or

granular nucleocapsids.⁷² Intranuclear Cowdry type A inclusion bodies are characteristic of morbillivirus infections and occur late in infection. CDV intranuclear inclusion bodies are usually complex nuclear bodies derived from nucleoli that contain N and a cellular heat shock protein.^{511,513} MeV N, when expressed alone, migrates to the nucleus^{309,680} where it can assemble into nucleocapsids that lack P and viral RNA and appear “smooth” by electron microscopy.^{140,512} Because binding of P to assembled nucleocapsids leads to cytoplasmic retention,³⁰⁹ it has been

postulated that the amount of P may be limiting late in infection, allowing N to move into the nucleus.^{72,309}

Budding

M plays a central role in virus assembly and release. In the absence of M, infectious particles are not released and expression of M alone leads to release of virus-like particles.^{102,109,556,611} To initiate virus assembly, M associates with the nucleocapsid, is co-transported to the plasma membrane,³²⁵ and interacts with the cytoplasmic domains of the F/H glycoprotein oligomers to promote virus budding.^{461,462,697} Proteins associate with detergent-resistant microdomains^{425,556,743} and budding is independent of the cellular endosomal sorting complex required for transport (ESCRT) system.⁶¹⁸ In polarized epithelial cells, budding is directed to the apical surface by the M protein despite the intrinsic glycoprotein targeting to the basolateral surface,^{418,487} and loss of apical targeting by M enhances cell-cell fusion at the expense of virus production.^{102,103,610}

Evolution, Antigenic Composition, and Strain Variation

Antigenically, MeV is a relatively stable virus. Antisera from individuals infected decades ago retain the ability to neutralize current wild-type strains of MeV and vice versa, although with varying efficiency.^{144,361,659} The observed rate of mutation of H in virus circulating in defined geographic locations is low, estimated at 5×10^{-4} per year for a given nucleotide,⁵⁹⁴ while the rate of mutation during growth *in vitro* is higher, estimated at 9×10^{-5} per replication for a nucleotide.⁶⁴⁴ Although historical accounts date the emergence of measles to approximately the 6th century (see History earlier), phylogenetic analysis of morbillivirus sequences suggests a more recent divergence from a common ancestor with RPV.²²² However, this more recent estimate may reflect the effects on sequence evolution of population bottlenecks after outbreaks and purifying selection to maintain protein function.^{222,561,769} The structure of H with carbohydrates masking the top surface and exposed receptor-binding sites on the side (Fig. 36.8) is postulated to constrain acquisition of mutations.^{276,608} Evidence of vaccine-induced selective pressure on wild-type strains of MeV has been identified in the noose and receptor-binding regions of H.^{209,236,623,658,659,713}

Nucleotide sequence variability, primarily in the N, P, and H genes, has been a useful tool for the MeV genotyping needed for molecular epidemiologic studies of transmission pathways.^{353,594,602} N genes differ by up to 7% in the C-terminal N_{TAIL} region, the region most often used for strain identification^{82,236} (Fig. 36.4). The P gene is most variable in the shared PV_{NTD},⁴⁵ and P gene sequencing has provided increased power to identify transmission routes when the N_{TAIL} sequences are identical.³⁵³ The H gene nucleotide sequence is most variable between residues 167 and 241 where the N-linked glycosylation sites are located, but can become regionally fixed.^{353,602}

Strains examined to date separate into eight different clades (A to H) and at least 24 different genotypes based on sequencing of the C-terminal 450 nucleotides of the N gene or the entire coding region of H.^{590,605,606,775,804} (Fig. 36.9). New genotypes are designated if the nucleotide sequence differs from the closest reference sequence by more than 2.5% in N or 2.0% in H.⁷⁷⁶ Some genotypes are found in one geographic region, others are co-circulating, while others are inactive and may be

extinct⁵⁹⁰ (Fig. 36.9). Live attenuated vaccines were all derived from genotype A wild-type strains and are quite similar.⁴⁶

PATHOGENESIS AND PATHOLOGY

Classic Measles

Measles is typically a childhood infection of humans spread by the respiratory route. Disease is characterized by a latent period of 10 to 14 days and a 2- to 3-day prodrome of fever, coryza, cough, and conjunctivitis followed by the appearance of a characteristic maculopapular rash (Fig. 36.10).³⁶² The onset of the rash coincides with the appearance of the immune response and initiation of virus clearance (Fig. 36.11). Recovery is accompanied by lifelong immunity to reinfection.⁵³⁰ Macaques exposed to infected humans or experimentally infected with wild-type strains of MeV develop a similar disease, and much of our more detailed understanding of pathogenesis, immune responses, and sites of virus replication come from studies of nonhuman primates, often facilitated by the use of engineered reporter viruses.^{29,143,146,441,735}

Entry and Sites of Primary Replication

MeV is efficiently transmitted over short distances by respiratory droplets and over longer distances by small-particle aerosols.^{119,617} High MeV infectivity suggests that the cellular sites of initial virus replication are very susceptible to infection. However, the nature of these cells is unclear because it has been difficult to identify MeV-positive cells in the respiratory tract at early times after infection.^{143,388} Although autopsy studies have shown abundant infection of respiratory epithelial cells,^{460,617} detailed studies of experimentally infected monkeys early after infection have only identified infected alveolar macrophages and subepithelial DCs.^{143,146,388} Because *in vitro* studies suggest that MeV infects epithelial cells from the basolateral

FIGURE 36.10. Measles virus rash.

FIGURE 36.11. Pathogenesis of measles. Measles virus (MeV) is spread by the respiratory route and replication begins in the respiratory tract and spreads to lymphocytes, monocyte/macrophages, endothelial cells, and epithelial cells in the blood, thymus, spleen, lymph nodes, liver, skin, and lung and to the conjunctivae and mucosal surfaces of the gastrointestinal, respiratory, and genitourinary tracts. The rash appears at the time of the virus-specific immune response with activation of MeV-specific CD4+ and CD8+ T cells and synthesis of MeV-specific immunoglobulin M (IgM) and IgG antibody. Clearance of infectious virus is approximately coincident with fading of the rash, but clearance of RNA is slower. Cytokines produced are consistent with activation of Th1 CD4+ and CD8+ T cells, followed by Th2 CD4+ T cells and regulatory cells. Immune suppression is initiated during the rash and persists for weeks after its resolution.

surface^{414,674} and MeV engineered not to infect respiratory epithelial cells can still initiate infection after intranasal inoculation,³⁹⁰ epithelial cell infection has been postulated to be a late, rather than an early, event. It is possible that pulmonary macrophages and DCs take up and transport MeV to local lymphoid tissue where virus is amplified, leading to viremia and subsequent systemic spread of infection to many tissues, including the lung.⁷⁰³

Spread

MeV interaction with DC-SIGN leads to up-regulation of SLAM on DCs, MeV entry,³¹ and likely transport from the respiratory tract to local lymphatic tissues in lung and draining lymph nodes.^{339,652,663} *In vitro* and *in vivo* studies suggest that DCs can transfer infection to susceptible T cells.^{143,148,663} Replication in lymphatic tissue is efficient, and infected CD150-expressing monocytes, T cells, and B cells are detected in peripheral blood within 4 to 7 days after infection.^{29,198,264,439,736} Only rarely has infectious virus been isolated from plasma,⁵³⁸ but viral RNA can be detected by reverse transcriptase-polymerase chain reaction (RT-PCR). MeV-infected mononuclear cells increase expression of the integrins LFA-1 ($\alpha_L\beta_2$) and VLA-4 ($\alpha_4\beta_1$) and transmembratory cups that promote adherence to endothelial cells and cell-to-cell transmission of infection.^{26,166,313,413} These properties likely facilitate virus dissemination. The viremia is accompanied by leukopenia due either to death of infected cells or to changes in leukocyte trafficking.^{29,517,613}

Target Cells and Tissues
